2008

## EXECUTIVE SUMMARY

There has been considerable enhanced oil recovery (EOR) activity in the North Sea. Eighteen of the 19 reported EOR projects have been gas processes. Most importantly, 16 of the 18 projects are economic successes. The outlook for EOR in the North Sea is promising.

In a contract signed August 27, 2007, we were authorized to conduct an EOR literature search and carry out model development work. This contract was preceded by an proposal dated August 24, 2007, and entitled “Proposal: Enhanced Oil Recovery (EOR) Field Data Literature Search.”

Not all reservoirs are amenable to EOR. Effective screening practices must be employed to identify suitable candidates. Economic evaluations require an estimate of the recovery performance. Empirical methods are invariably used to predict performance for early evaluations. The objective of our literature search was to collect enough field data to develop an empirical model to predict the oil-rate history of a prospect reservoir. Owing to past and current EOR trends in the North Sea, efforts focused on miscible gas EOR.

We have successfully developed an EOR rate model. This model is based on hyperbolic decline curves and material balance. The model effectively matches the production history of tertiary miscible floods. The model can easily be incorporated into pre-existing discounted cash-flow models.

The public literature is rich in EOR field data references. Over 390 papers were collected on 70 separate miscible gas projects. Our search sought rate history data with specific supplemental information. The process of gathering and analyzing papers was very time-consuming but informative. In the end, seven case histories suitable for validating the empirical model were identified. All of the cases were onshore U.S. CO<sub>2</sub> floods. Additional testing, however, is needed as new data becomes available. The model is simple enough to add such data.

The work here also includes compiled sets of screening criteria from our literature search. The screening criteria are informative.

In summary, the results of this work should be helpful in evaluating prospects for gas injection EOR.

# **ENHANCED OIL RECOVERY (EOR) FIELD DATA LITERATURE SEARCH**

## **INTRODUCTION**

One definition of enhanced oil recovery (EOR) is "the recovery of oil by injection of a fluid that is not native to the reservoir." EOR is a means to extend the productive life of an otherwise depleted and uneconomic oil field. It is usually practiced after recovery by other, less risky and more conventional methods, such as pressure depletion and waterflooding, have been exhausted.

Not all reservoirs are amenable to EOR. Effective screening practices must be employed to identify suitable candidates. As part of the screening, discounted cash-flow projections are routinely performed to assess profitability. At the core of these projections is an estimate of recovery performance. In the initial screening studies, invariably, performance predictions from numerical simulation studies are not yet available. Therefore, other methods—usually empirical—are needed to estimate future performance.

## **OBJECTIVES**

The objectives of this work are:

1. To carry out a current literature search for enhanced oil recovery (EOR) case histories (oil rate vs. time);
2. To document, categorize, and inventory the literature search;
3. To use the rate histories to develop a non-simulation (empirical) predictive model;
4. To carry out a current literature search for screening criteria for the different EOR processes;
5. To summarize the screening criteria for the different EOR methods; and
6. To submit an electronic archive of the literature search.

The purpose of the predictive model is to provide an approximate method to estimate the rate history for candidate reservoirs. The model is intended for scoping or screening studies.

## **AUTHORITY**

This report was authorized by Mr. Peter Helmer Steen, Director General, of the Danish North Sea Partner, Ministry of Transport and Energy. Mr. Steen was the project manager.

## NORTH SEA EOR

There have been 19 past or current EOR projects in the North Sea, according to a 2006 survey (Awan, et al. 2006). Eighteen of the 19 projects have been or are gas EOR projects; the remaining project is a microbial EOR project. Table 1 lists the project reservoirs, operator, country sector, and type of gas EOR project.

Twelve of the 18 gas EOR projects are located in the Norwegian sector; 5 in the United Kingdom (UK) sector; and one project in the Danish sector. All of the projects have used hydrocarbon (HC) gas as the EOR injectant. Sixteen of the projects have used lean gas; 2 have used rich gas.

Based on past and current activity, most operators feel gas EOR is the most promising method for North Sea reservoirs. This is not surprising inasmuch as North Sea reservoirs fit many of the criteria for miscible EOR application. They are deep enough to permit the high pressures required to attain miscibility and often contain sufficiently light and low-viscosity oils, both characteristics that are ideal for miscible EOR.

Not only do North Sea reservoirs appear amenable to gas EOR, but most (16 of the 18) have already been proven successful. The confidence in success is evidence by the willingness of some operators to implement projects (six of the 18) even though the miscibility pressure cannot be attained. These projects were classified as immiscible. Nine of the 18 projects were classified as miscible, and three of the projects were unclassified according to miscibility. We use the term solvent flooding to describe these types of floods.

*Table 1. North Sea EOR Projects (Awan, et al., 2006)*

FIELD	OPERATOR	SECTOR	TYPE	START DATE	SUCCESS
Ekofisk	ConocoPhillips	Nor.	HC Miscible <sup>1</sup>	1971	Success
Beryl	Exxon-Mobil	UK	HC Miscible	1976	Success

Ekofisk	ConocoPhillips	Nor.	HC WAG Immiscible	1971	
Statfjord	Statoil	Nor.	HC WAG Immiscible	1979	Success
Oseberg	Norsk Hydro	Nor.	HC WAG Immiscible	1999	Success
Siri	Statoil	Danish	HC SWAG*	1999	Success
Snorre A (CFB)	Norsk Hydro	Nor.	HC FAWAG	1992	
Snorre A (WFB)	Norsk Hydro	Nor.	HC FAWAG	1992	Success

FAWAG = foam-assisted WAG

SWAG = simultaneous water-and-gas injection

\* Principally a gas-storage project.

<sup>1</sup> Not currently operational (Damgaard, 2008).

<sup>2</sup> In blowdown phase; not EOR project (Damgaard, 2008).

<sup>3</sup> In EOR study phase (Damgaard, 2008).

## SCOPE OF INVESTIGATION

We originally proposed investigating chemical EOR methods in this work. Other EOR methods were omitted because they either lacked applicability for North Sea conditions or lacked general reliability. For example, we did not investigate steamflooding because North Sea reservoirs are too deep and above the pressure limits for successful application. Alkaline flooding was not included because it is considered a developing and unproven technology.

There is a decided trend toward gas EOR in the North Sea (Awan, et al., 2006). Solvent EOR has been technically proven to be commercially successful worldwide. On the other hand, there has been no commercial chemical EOR activity in the North Sea, despite ongoing interest. Fayers et al. (1981) point out the difficulties in finding suitable polymers and low-cost surfactants for North Sea temperatures and salinities. Jensen et al. (2000) discount chemical EOR as a viable alternative in their study of Ekofisk.

In addition, though there is substantial current interest, the worldwide commercial success with chemical EOR has been marginal. According to an Oil and Gas Journal (2006) report, the worldwide chemical EOR production is less than 15,000 barrels/day,<sup>1</sup> with all of the production coming from only Chinese polymer floods, and no production from surfactant-polymer flooding. Recognizing these trends, we focused efforts on gas EOR. We will include qualitative descriptions of chemical EOR, in-situ combustion, electromagnetic heating, carbonated waterflooding, microbial EOR, and caustic/alkaline flooding.

## EOR METHODS

All of currently available EOR is based on one or more of two principles: increasing the capillary number and/or lowering the mobility ratio, compared to their waterflood values. Increasing the capillary number means, practically speaking, reducing oil-water interfacial tension. The injectant mobility may be reduced by increasing water viscosity, reducing oil viscosity, reducing water permeability or all of the above.

Using the nomenclature adopted by the Oil and Gas Journal, EOR processes are divided into four categories: thermal, gas, chemical, and other. Table 2 summarizes the main processes within each category. The processes are typically defined by the nature of their injected fluid. For instance, gas EOR includes hydrocarbon miscible/immiscible and CO<sub>2</sub> miscible and immiscible processes.

### **Gas EOR Methods**

These methods are capillary number increasing methods. They are also called solvent flooding, miscible-gas flooding or simply gas flooding. The injectant can be dry gas, enriched gas (hydrocarbon miscible), CO<sub>2</sub>, nitrogen or flue gas, or combinations of these.

---

<sup>1</sup> All units in this report are expressed in English or oilfield units. For conversion factors to SI or metric units, see the Conversion Factors section near the end of this report.

Table 2. EOR categories and processes.

**Thermal EOR processes**

Steamflooding  
Cyclic steam stimulation  
In-situ combustion  
Hot waterflooding  
Steam-assisted gravity drainage

**Gas EOR processes**

Hydrocarbon miscible/immiscible  
CO<sub>2</sub> miscible  
CO<sub>2</sub> immiscible  
Nitrogen  
Flue gas (miscible and immiscible)  
Gravity drainage

**Chemical EOR processes**

Micellar-polymer  
Polymer  
Caustic/alkaline  
Alkaline/surfactant

**Other EOR processes**

Carbonated waterflood  
Microbial  
Electromagnetic heating

Solvent methods recovery oil by mass transfer. For some processes, the mass transfer of intermediate hydrocarbon components is from the crude to the solvent (vaporizing gas drive) and for others the transfer is from the solvent to the crude (condensing or rich gas drives). CO<sub>2</sub>, nitrogen or flue gas are vaporizing gas drives and hydrocarbon miscible drives are the latter. In all cases it is the intermediate component, the component that is doing the transferring, that is key.

If the reservoir pressure is large enough (or if there is sufficient intermediate content at the current pressure), the mass transfer will result in a mixture that is miscible with the crude, in which case the predominant recovery mechanism is a miscible displacement. In a miscible displacement, interfacial tension vanishes and capillary number becomes infinite. Failing this, the displacement will be immiscible. Immiscible displacements are not as efficient as miscible displacements but may still recover oil by swelling, viscosity reduction or permeability increase, or pressure build up. CO<sub>2</sub> and enriched hydrocarbons tend to be miscible solvents; nitrogen and flue gas tend to be immiscible.

Miscible displacements in the laboratory result in nearly 100% ultimate oil recoveries. Field-scale displacements recover much less, primarily because the solvent tends to be more mobile than the oil/water mixtures they are displacing, which leads to bypassing of the solvent around or through the oil. Bypassing is the result of reservoir heterogeneity and viscous instability between two fluid fronts. Some types of heterogeneity can result in substantial mixing in the reservoir and a loss of miscibility.

The bypassing can be eliminated or at least reduced by co-injection of water with the solvent (the WAG process), conducting the flood in a gravity stable mode and/or using foams to reduce the gas mobility.

Most of the reported results have been on CO<sub>2</sub> solvent flooding in the US wherein ultimate recoveries of 12% of the original oil in place and utilization factors of 10 MCF

solvent/incremental barrel of oil recovered are reported. These performances translate into chemical costs of 10-30 \$/incremental bbl, depending on performance, and the cost of the solvent. Many potential CO<sub>2</sub> injection projects are on hold because of the lack of solvent.

### **Chemical EOR Methods**

These methods are increasing capillary number processes (micellar-polymer, caustic/alkaline) or mobility ratio processes (polymer). All are based on injecting one or more chemicals into a reservoir to bring about the aforementioned changes.

**Polymer Flooding.** Polymer methods consist of injecting an aqueous phase (water, or brine) into which has been dissolved a small amount of a polymeric thickening agent. The thickening agent increases water viscosity and in some cases lowers the permeability to the phase to bring about the lowered mobility ratio. Polymer methods do not increase capillary number.

Primarily because of its small cost, there have been more polymer floods done than any other type of EOR process. Unfortunately most of these were take advantage of an artificial taxing policy in the US and not to recover much incremental oil. With the lapsing of the policy and the collapse of the oil price in the mid 80s, these projects virtually disappeared, giving way to a variation of the process based on polymer gels. With the restoration of the oil price, interest has picked up, especially because of the significant reported successes in the Chinese Daqing Field. Polymer processes have historically recovered about 5% of the original oil in place and taken about 1 lbm of polymer to produce an incremental barrel.

**Micellar-Polymer Flooding.** Micellar-polymer processes are similar to polymer process but with the addition of a surfactant to the injectant. The surfactant reduces oil-water interfacial tension making this process both a mobility ratio decreasing and a capillary number increasing process. This process virtually disappeared in the low price environment of the 80s but is experiencing revitalization, though as yet there are no current field projects. MP processes recover about 15% of the original oil in place, but there are not economical at oil prices less than about 30\$/bbl.

**Alkaline Flooding.** Caustic/alkaline processes are an attempt to use the interfacial tension lowering properties of natural surfactants that exist in many crudes. A highly interesting innovation with this process is the use of a small amount of co-surfactant in the so-called alkaline surfactant process. Field experience is immature, but initial report suggest that incremental oil can be recovered for 20-25\$/bbl.

### **Thermal EOR Methods**

Thermal methods lower mobility ratio by decreasing oil viscosity. Since the effect of temperature is especially pronounced for viscous crudes, these processes are normally applied to heavy crudes. This "niche" is actually quite large world wide, consisting of more in-place hydrocarbon than light crudes. An approximate classification of viscous crude oils based on reservoir conditions viscosity is as follows:

viscosity less than 1,000 cp	heavy crude
1000 to 100,000 cp	tar sand
100,000 to 1,000,000 cp	bitumen or oil shale

Besides being aimed at viscous crudes, thermal methods will be successful if there is a rigorous heat management procedure in place. This means that heat losses are to be minimized as much as possible. Heat loss sources are:

1. Losses to rock and water - minimized by restricting application to reservoirs with small water saturation, large porosities or small shale content.
2. Losses to surface equipment - normally the smallest heat loss source, this is minimized by insulating surface lines and minimizing line length.
3. Losses to wellbores - minimizing wellbore heat loss is done by restricting application to shallow reservoirs. Heat loss in this manner can be controlled by insulating downhole tubulars, generating heat down hole, using in-situ combustion, injecting the steam at high rate or evacuating the production casing.
4. Losses to adjacent strata - minimizing this form of heat loss means minimizing the producing life of the field (normally done with small well spacing) or restricting application to thin reservoirs.

**Cyclic Steam Stimulation.** CSS is also known as steam soak, or huff and puff. In this process steam is injected into a well bore out to a heated radius of a few tens of meters. Then the original steam injector is converted to a producer and a mixture of steam, hot water, and oil produced. CSS is the most common steam injection process today. Most of the time most of the wells are producers: there are no dedicated injectors. CSS is often used as a precursor to steam drive discussed next.

**Steam Drives.** Also known as steam flooding, in this process steam is injected into dedicated wells and the fluids driven to a separate set of producers. Combined CSS and steam drives often recover more than 50% of the original oil in place. This combination is the first commercial EOR process and has been so since the mid 50s. Perhaps more than 2 billion barrels of oil have been produced in this manner to date.

**In-situ Combustion.** This process is an attempt to extend thermal recovery technology to deeper reservoirs and/ or more viscous crudes. In recent years it has become known as high-pressure air injection. In-situ combustion recovers 10-15% of the original oil in place.

## INVENTORY OF PAPERS

The literature search was confined to papers dealing with gas-flood case histories and limited to papers in the Society of Petroleum Engineers (SPE) electronic library, with a few exceptions. We collected almost 400 papers. Appendix A shows a listing of the papers. The Excel file “EOR\_Paper\_Inventory” contains an electronic listing with additional information about the papers, such as SPE paper number, EOR method (hydrocarbon miscible, CO<sub>2</sub> miscible, CO<sub>2</sub> huff-n-puff, or immiscible), field, paper date, and whether the paper contained rate data or not. See Electronic Attachment A on the accompanying Compact Disc (CD).

The papers included over 130 different gas EOR projects, ranging from large-scale commercial projects to small-scale pilot projects, including immiscible and miscible projects. Table 3 lists most of the projects.

The papers are in the Paper Archive, Electronic Attachment B on the accompanying Compact Disc (CD). The papers are in Portable Document Format (PDF) and can be read by the Adobe Acrobat Reader software. The paper archive is over 340 megabytes (MB) in size.

The overall purpose the literature search was to identify useful field data for model development work. Specifically, we sought to locate as many solvent flood oil-rate

histories as possible. The next section describes the process of transforming the literature search into a useable database of case histories.

## **DATABASE OF CASE HISTORIES**

The process of reviewing, analyzing, and cataloging the papers went through several steps or rounds of elimination before identifying useable case histories. In this section, we describe the method used to arrive at the final database.

In the first round, we eliminated papers that contained no oil-rate history data. This step left about 59 papers.

In the second round, we began scrutinizing the rate data. We eliminated some projects on relatively obvious grounds. For instance, secondary miscible projects were omitted because North Sea applications would likely be tertiary projects. This criterion removed some notable projects such as Crossett North Cross Unit, SACROC (Phase 1), and Wizard Lake. We omitted a few floods because they started shortly after waterflooding. This group included the Hanford (CO<sub>2</sub> injection started after only 1 year of water injection) and the Wasson Willard Unit (CO<sub>2</sub> flood started after only 30% of a pore volume of injected water) floods. The Willard Unit flood also had other limitations.

Heavy oil or immiscible projects were eliminated, as were gas-cycling or gravity-drainage projects. Also, CO<sub>2</sub> huff-n-puff projects were eliminated. Some older projects from the 1950's and early 1960's were eliminated because they involved such inordinately small solvent slug sizes that they performed poorly. Also, some projects were eliminated because the reports were illegible or overly ambiguous.

None of the references to North Sea projects contained useful data. Most of the references dealt with immiscible projects. Some of these immiscible projects, such as the foam-assisted WAG projects, were designed to only reduce gas production or improve sweep efficiency.

After the first two rounds of elimination, about 22 projects remained. Most of these projects are shown in Table 4. This group represented cases of special interest.

To screen these projects further, a data checklist was created to extract desirable data from papers for each solvent flood. Most of the checklist items were closely connected to model parameters to be discussed later. Some of the items, however, were selected because they might be correlating parameters, such as reservoir permeability and well spacing. The data checklist actually evolved over time. Items were added and deleted as our modeling work progressed. Table 5 is the final checklist.

\* Denotes critical item

The checklist data items were divided into critical (an asterisk in Table 5) and non-critical groups. A checklist was completed for each solvent flood, paying special attention to the critical items. If the accumulated references for a subject flood did not ultimately provide the critical items, the flood was not considered further. For instance, if the flood references did not provide information about the project's injection rate, pore volume, or original oil in place (or this information could not be reasonably estimated), the flood was eliminated from further consideration.

Several prominent floods were eliminated because a lack of data or anomalies. The following describes some of our experiences.

The literature for some projects furnished rate data but failed to provide supporting critical data. This group included the Rangely Weber Sand Unit and Dollarhide. A majority of projects, also for instance, provided only very preliminary production data, such as production for only 1 or 2 years after solvent injection. The production history data was often terminated shortly after an initial oil response and before a peak oil rate was observed. This group of floods included the Sundown Slaughter Unit, Goldsmith, Hanford San Andres, and Weyburn. Though most of these floods have been completed or are very nearly completed, the public literature does not contain a complete record.

Also, just having a field's complete rate history is not enough. It is critical to know certain operational aspects as will be illustrated below.

Some of the larger floods were staged in their development. In a staged development one segment of the field would be flooded before another. Instead of reporting the production history for individual sections, operators would lump together all the production data and only report the performance of the entire field. The commingling of production data made meaningful analysis of the Salt Creek, Rangely Weber Sand, and Wasson Denver Unit difficult.

Another complication occurred with the Means Unit miscible flood. This was a promising case with considerable information, but the operators implemented a large infill-drilling program coinciding with the miscible flood. It was impossible to distinguish the rate response to miscible flooding and infill drilling.

The Ford Geraldine Unit flood was plagued by severe solvent supply deficiencies. Occasionally, the flood almost had to be shut down. This greatly affected the history and complicated interpretation. For instance, most tertiary miscible floods initially respond within a few months. At the Ford Geraldine Unit, however, the initial response was delayed over six years. While the flood was ultimately very successful, certain aspects of the rate history were anomalous. Consequently, the flood was eliminated from consideration.

Another anomaly was the Rangely Weber Sand Unit. This prominent CO<sub>2</sub> flood had significant injectivity loss. While injectivity loss is common in many solvent floods, it appeared to be worse than usual at Rangely. The lost injectivity resulted in significant rate losses that contributed to an attenuated oil response. (The fact that the flood was staged over 7 years and never covered the entire field also likely contributed.)

Figure 1 shows the rate history for the Rangely flood. This history includes the produced oil and water rates. CO<sub>2</sub> was injected in late 1986. Notice that the oil rate increased only about 10% over pre-flood levels; however, the produced water rate decreased significantly. The net result was that the produced oil cut increased significantly but the oil rate did not. Figure 2 confirms the oil cut response, as reported by the operators. The oil cut increased from about 5.8% to a peak cut of almost 9%. This peak oil cut is typical for most successful miscible floods; however, the rate response is atypical. Without injectivity loss, the data in Fig. 2 predicts the oil rate would have increased over 55%.

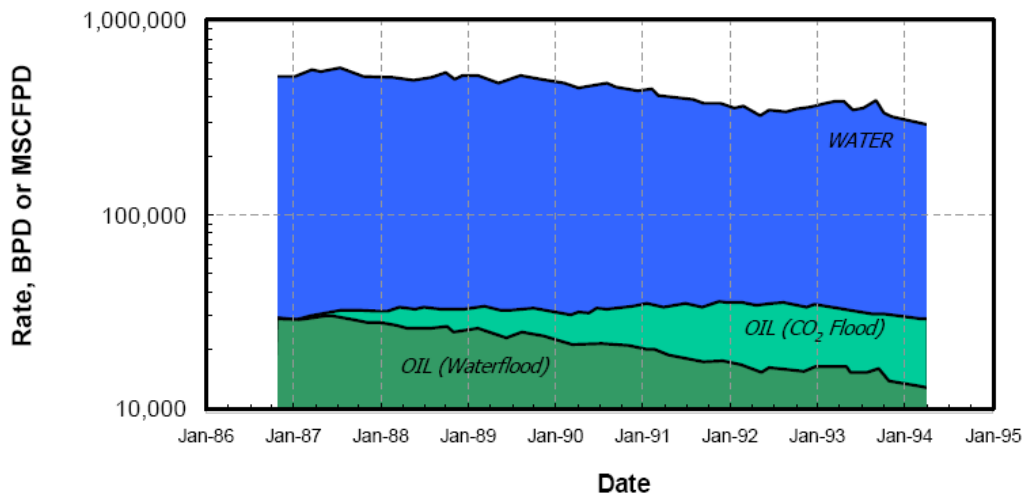

Figure 1. Rangely Weber Sand Unit miscible-flood production history. The curve above the blue area is the produced water rate history; the curve above the light green area is the produced oil rate history; the curve above the dark green curve is the expected oil rate history if waterflooding was continued.

Figure 2. Rangely Weber Sand Unit oil cut history. The shaded gray region is the waterflood; the shaded green region is the CO<sub>2</sub> flood.

Considering the above, we were able to identify seven useable complete histories: the CO<sub>2</sub> flood in the east side of the Twofreds field (Thrash, 1979; Flanders and DePauw, 1993; Kirkpatrick et al., 1985), the Lost Soldier CO<sub>2</sub> flood (Brokmeyer et al., 1996), the Wertz CO<sub>2</sub> flood (Kleinsteiber, 1990), the Slaughter Estate Unit (SEU) CO<sub>2</sub> pilot (Rowe, 1982; Stein et al, 1992), the West Sussex Unit CO<sub>2</sub> pilot (Holland, et al., 1986), the SARCOC Four-Pattern Area (4PA) CO<sub>2</sub> flood (Langston, et al., 1988), and the SACROC Seventeen-Pattern Area (17PA) CO<sub>2</sub> flood (Langston, et al., 1988). Coincidentally, all of the complete histories were CO<sub>2</sub> floods and onshore projects. Five of the seven projects were commercial projects; the West Sussex Unit test was a pilot but used commercial-scale well spacing. Table 6 constitutes the database for the modeling work.

\* Denotes critical data

The Twofreds, Wertz, and Lost Soldier floods are discussed in the Model Applications section and will not be reviewed here. The Slaughter Estate Unit and West Sussex Unit pilots and the SACROC Four Pattern and Seventeen Pattern floods are discussed briefly below.

**Slaughter Estate Unit CO<sub>2</sub> Pilot.** Discovered in 1937, the Slaughter field is in west Texas, USA. Amoco was named operator of the Slaughter Estate Unit in 1963 when waterflooding began. They conducted a CO<sub>2</sub> pilot test in a 12-acre double five-spot area that was not previously waterflooded. The well spacing was only 3 acres. This case was unique in that it employed much smaller well spacing than all other cases in the database. The primary recovery in the pilot area was 9.6% of the OOIP. A pilot waterflood recovered 29.9% of the OOIP. Alternate injection of acid gas (72% CO<sub>2</sub> and 28% H<sub>2</sub>S) and water began in August 1976. The WAG ratio was approximately 1. The cumulative tertiary oil recovery was 30.8%. The incremental oil recovery was 19.6%.

**West Sussex Unit CO<sub>2</sub> Pilot.** Discovered in 1951, the West Sussex Shannon reservoir is located in Wyoming, USA. Full-scale waterflooding began in 1959. The cumulative recovery from primary and secondary operations was 18.1 and 24.1%, respectively.

Conoco conducted a CO<sub>2</sub> pilot in a previously waterflooded portion of the field. Covering 9.6 acres, the waterflood was a diagonal half of an inverted five-spot (one injector and three producers). Though a pilot test, the well spacing was 9.6 acres and representative of field-scale spacing. Continuous CO<sub>2</sub> injection started in December 1982. The pre-flood oil cut was 1%; the peak oil cut was 21%. The ultimate cumulative tertiary recovery was 9.5%.

**SACROC Four-Pattern CO<sub>2</sub> Flood.** Discovered in 1948, the Kelly-Snyder field is last billion-barrel field found in the continental US. Located in west Texas, the field covered over 84,000 acres. Under solution-gas drive, primary recovery was 19% of the OOIP. In March 1953, the SACROC unit was formed to improve oil recovery from water injection.

In 1968, Chevron began studying the use of CO<sub>2</sub> to improve recovery. The field was divided into three areas (phases). CO<sub>2</sub> injection began in Phase 1 in January 1972. Before CO<sub>2</sub> injection, Phase 1 was only marginally waterflooded; thus, this CO<sub>2</sub> flood was considered a secondary recovery project. Pattern waterflooding began in 1972 in Phase 2 and in 1973 in Phase 3.

In June 1981, CO<sub>2</sub> injection began in a 600-acre area of Phase 3. This area consisted of three 160-acre inverted 9-spot patterns and one smaller irregular pattern. This area was called the Four-Pattern Area (4PA). The 4PA contained 22 wells, including 4 injectors.

Before CO<sub>2</sub> injection, the 4PA was thoroughly waterflooded. Chevron estimated an ultimate waterflood recovery of 21.7% of the OOIP. Alternate CO<sub>2</sub> and water injection resulted in an estimated cumulative tertiary recovery of 14.4 % and an incremental recovery of 10.2%. The average WAG ratio was 3. The well spacing was 40 acres.

**SACROC Seventeen-Pattern CO<sub>2</sub> Flood.** Chevron conducted a CO<sub>2</sub> flood in another area of Phase 3 of SACROC. This area covered over 2,700 acres and included 17 patterns and over 100 wells. The area was previously subject to pressure depletion and waterflooding before CO<sub>2</sub> injection. Alternate CO<sub>2</sub> and water injection began in May

1981. Chevron used an average WAG ratio of 5. The ultimate incremental recovery was projected at 7.5% of the OOIP. The well spacing was 40 acres.

The data items in the database were divided into two classes: primary and computed items. Primary items came directly from the case histories; in contrast, the computed items were derived from the primary items.

Appendix B presents a catalogue of many of the rate histories we encountered in our literature search.

### **Summary**

The purpose of the literature search was to identify field data for model development work. Our search was very specific. We sought complete or near-complete rate histories along with some very specific supplemental information.

Initially, we identified about 59 miscible flooding projects with rate history data. This group included many projects or processes outside our scope of interest. Only 22 of these projects were significant enough for serious consideration. In the end, seven projects met our qualification criteria. Though we did not find as much useful data as we originally expected, the gathered data was sufficient for modeling. The modeling work is discussed in the next section.

## EOR RATE MODEL

This section presents work to formulate, develop, and test an EOR rate model to predict the oil-rate history of a tertiary miscible flood. Our approach is intended for scoping or screening studies.

### **Approach**

Our approach is based on hyperbolic decline curves and material balance. Figure 3 shows a schematic oil rate history from the end of a waterflood and through a solvent flood. The solid black curve shows the rate history; the shaded blue and green portions the waterflood and solvent flood, respectively. Time  $t_1$  is the date of the start of solvent injection.

Our approach is similar to the work of Bush and Helander (1968) who investigated the problem of empirically modeling the oil rate history of a waterflood. For a reservoir previously subject to pressure depletion, they divided the waterflood history into three distinct periods: fill-up; a period of rapidly increasing oil rate; and a final period of rate decline. In the first period, the oil rate was constant and equal to the rate at the end of pressure depletion. In the second period, the oil rate increased exponentially. In the final period, the rate decreased exponentially.

The EOR history is divided into three time periods: (1) from  $t_1$  to  $t_2$ , (2) from  $t_2$  to  $t_3$ , and (3) from  $t_3$  to  $t_4$ . Time  $t_2$  is the time (date) immediately before an EOR oil response; time  $t_3$  is the time (date) of the peak oil rate; and time  $t_4$  is the end of the EOR process.

To model these three time periods, we use the following assumptions. Between times  $t_1$  and  $t_2$ , the rate decreases according to an extrapolation of the decline of previous production. Usually this is a waterflood decline curve. Between times  $t_2$  and  $t_3$ , the oil rate increases linearly with time. And after time  $t_3$ , the rate follows a hyperbolic decline curve. The dashed blue curve in Fig. 3 shows the waterflood decline curve; the dashed red curve shows the model EOR rate history.

Though an oversimplification, the model is more than adequate for screening and economic evaluations. In the following sections we present the defining equations, procedures to estimate model parameters, and model applications. An important part of the work is the development of effective empirical relationships to estimate model parameters. The empirical relationships are based upon production trends observed in published field case histories. The case histories were gathered from the literature search discussed above.

Figure 4. Key oil rates and cumulative recovery parameters in the EOR rate model.

where  $b_{WF}$  and  $b_{EOR}$  are the decline (Arps) exponents of the decline curves for the waterflood and solvent flood, respectively;  $D_{iWF}$  and  $D_{iEOR}$  are the initial decline rates of the decline curves for the waterflood and solvent flood, respectively;  $q_{iWF}$  is the initial rate of the waterflood decline curve; and  $t_{iWF}$  is the time corresponding to  $q_{iWF}$ .

The rates  $q_1$  and  $q_2$  are determined from the waterflood decline curve

$$q_1 = \frac{q_{iWF}}{[1 + b_{WF} D_{iWF} (t_1 - t_{iWF})]^{1/b_{WF}}} \quad (2)$$

$$q_2 = \frac{q_{iWF}}{[1 + b_{WF} D_{iWF} (t_2 - t_{iWF})]^{1/b_{WF}}} \quad (3)$$

**Oil Recovery.** The oil recovery from the start of solvent flooding is

$$N_p(t) = \frac{q_{iWF}^{b_{WF}}}{D_{iWF} (1 - b_{WF})} \left[ \frac{1}{q_1^{(b_{WF}-1)}} - \frac{1}{q(t)^{(b_{WF}-1)}} \right], \quad \text{for } t_2 > t > t_1 \quad (4a)$$

$$N_p(t) = N_{p2} + \frac{(t-t_2)}{2}(q(t) - q_2), \quad \text{for } t_3 > t > t_2 \quad (4b)$$

$$N_p(t) = N_{p3} + \frac{q_{\text{peak}}^{b_{\text{EOR}}}}{D_{\text{iEOR}}(1-b_{\text{EOR}})} \left[ \frac{1}{q_{\text{peak}}^{(b_{\text{EOR}}-1)}} - \frac{1}{q(t)^{(b_{\text{EOR}}-1)}} \right], \quad \text{for } t > t_3 \quad (4c)$$

where  $N_{p2}$  and  $N_{p3}$  are

$$N_{p2} = \frac{q_{\text{iWF}}^{b_{\text{WF}}}}{D_{\text{iWF}}(1-b_{\text{WF}})} \left[ \frac{1}{q_1^{(b_{\text{WF}}-1)}} - \frac{1}{q_2^{(b_{\text{WF}}-1)}} \right] \quad (5)$$

$$N_{p3} = N_{p2} + \frac{(t_3 - t_2)}{2}(q_{\text{peak}} + q_2) \quad (6)$$

The recoveries in Eqs. (4) – (6) are the cumulative oil recovered from the start of solvent injection.

**Projected Waterflood Recovery.** If waterflooding were hypothetically continued after  $t_1$  instead of switching to solvent injection, the projected or hypothetical oil rate would follow an extension of waterflood decline curve. Accordingly, the oil rate would be

$$q_{\text{WF}}(t) = \frac{q_{\text{iWF}}}{[1 + b_{\text{WF}} D_{\text{iWF}}(t - t_{\text{iWF}})]^{1/b_{\text{WF}}}}, \quad \text{for } t > t_{\text{iWF}} \quad (7)$$

The projected incremental oil recovery after  $t_1$  is

$$\Delta N_{\text{pWF}}(t) = \frac{q_{\text{iWF}}^{b_{\text{WF}}}}{D_{\text{iWF}}(1-b_{\text{WF}})} \left[ \frac{1}{q_1^{(b_{\text{WF}}-1)}} - \frac{1}{q_{\text{WF}}(t)^{(b_{\text{WF}}-1)}} \right], \quad \text{for } t > t_1 \quad (8)$$

**Incremental Oil Recovery.** The incremental oil recovery is the volume of oil recovered in excess of continued waterflooding given by

$$\Delta N_p(t) = N_p(t) - \Delta N_{\text{pWF}}(t), \quad \text{for } t > t_1 \quad (9)$$

For instance, if the cumulative oil recovery after solvent injection is 11 million barrels and the cumulative recovery from continued waterflooding is estimated at 1 million barrels, then incremental recovery is 10 million barrels.

**Dimensionless Recovery Equation.** Equation (4c) can be put in a dimensionless form with the following definitions:

$$N_{pD} = \frac{N_p}{N} \quad (10)$$

$$\Delta t_D = \frac{Q_T \Delta t}{V_p} \quad (11)$$

$$D_D = \frac{D_{iEOR} V_p}{Q_T} \quad (12)$$

$$f_{opeak} = \frac{q_{peak}}{Q_T} \quad (13)$$

$$f_{o2} = \frac{q_2}{Q_T} \quad (14)$$

where  $N$  is the OOIP,  $Q_T$  is a characteristic injection rate,  $\Delta t$  is an elapsed time (since the start of solvent injection), and  $V_p$  is the reservoir pore volume.  $D_D$  represents a dimensionless decline-rate constant. The characteristic rate is defined

$$Q_T = B_s Q_s + B_w Q_w \quad (15)$$

where  $Q_s$  is the field (flooded area) injected solvent rate, expressed in surface volume per unit time (e.g., scf/day or  $\text{sm}^3/\text{day}$ );  $Q_w$  is the field (flooded area) injected water rate, expressed in surface volume per unit time;  $B_s$  is the solvent formation volume factor; and  $B_w$  is the water formation volume factor.  $B_s$  is measured at the average reservoir pressure and temperature. In the absence of data, we assume  $B_w = 1$ . For continuous solvent injection,  $Q_w$  is zero; for alternate solvent-water injection,  $Q_s$  and  $Q_w$  are both non-zero.  $Q_T$  is injected fluid rate expressed in reservoir volume per unit time.

The variables  $f_{opeak}$  and  $f_{o2}$  represent effective oil cuts. The true oil cut is the produced oil rate normalized by the sum of the produced surface water and oil rates. In contrast,  $f_{opeak}$  and  $f_{o2}$  are produced oil rates normalized by  $Q_T$ , which is expressed as a reservoir rate. Substituting Eq. (6) into Eq. (4c) and using the definitions from Eqs. (10) – (14), Eq. (4c) becomes

$$N_{pD}(t) = N_{p2D} + \frac{(\Delta t_{D3} - \Delta t_{D2})(f_{opeak} + f_{o2})B_{oi}}{2(1 - S_{wi})} + \frac{f_{opeak} B_{oi}}{D_D(1 - S_{wi})(1 - b_{EOR})} \left[ 1 - \left( \frac{f_o(t)}{f_{opeak}} \right)^{1-b_{EOR}} \right] \quad (15)$$

where  $S_{wi}$  and  $B_{oi}$  are the initial (at discovery) water saturation and oil formation volume factor and  $f_o$  is the oil cut at arbitrary time  $t$ . The equation  $N = V_p(1-S_{wi})/B_{oi}$  is used to help derive Eq. (15). Equation (15) also uses the following definitions:

$$\Delta t_{D3} = \frac{Q_T \Delta t_3}{V_p} \quad (16)$$

$$\Delta t_{D2} = \frac{Q_T \Delta t_2}{V_p} \quad (17)$$

$$N_{p2D} = \frac{N_{p2}}{N} \quad (18)$$

where  $\Delta t_3 = t_3 - t_1$  and  $\Delta t_2 = t_2 - t_1$ . Equation (15) is a material balance on the produced oil. The variables  $\Delta t_{D2}$  and  $\Delta t_{D3}$  represent dimensionless times. Physically,  $\Delta t_{D2}$  is the pore volumes of fluid injected (PVI) at oil bank breakthrough;  $\Delta t_{D3}$  is the PVI at the peak oil rate. Their significance will be discussed later.

Another important dimensionless time—one corresponding to project termination is

$$\Delta t_{D4} = \frac{Q_T \Delta t_4}{V_p} \quad (19)$$

where  $\Delta t_{D4}$  is the PVI at termination and  $\Delta t_4 = t_4 - t_1$ . The variable  $\Delta t_{D4}$  represents the flood life expressed in PVI. Using  $\Delta t_{D4}$ , Eq. (15) can be put into a slightly different form. If we evaluate Eq. (1c) at  $t = t_4$ , cast the equation in dimensionless form, and then solve for  $D_D$ , we obtain

$$D_D = \frac{\left( \frac{f_{opeak}}{f_{o4}} \right)^{b_{EOR}} - 1}{b_{EOR} (\Delta t_{D4} - \Delta t_{D3})}, \quad (20)$$

where  $f_{o4}$  is the oil cut at time  $t_4$ .  $f_{o4}$  is the oil cut at termination. It is a function of economic factors and is approximately 0.01-0.04. Substituting Eq. (20) into Eq. (15) gives

$$N_{p4D} = N_{p2D} + \frac{(t_{D3} - t_{D2})(f_{\text{opeak}} + f_{\text{o2}})B_{\text{oi}}}{2(1 - S_{\text{wi}})} + \frac{f_{\text{opeak}} B_{\text{oi}} b_{\text{EOR}} (\Delta t_{D4} - \Delta t_{D3})}{\left[ \left( \frac{f_{\text{opeak}}}{f_{\text{o4}}} \right)^{b_{\text{EOR}}} - 1 \right] (1 - S_{\text{wi}}) (1 - b_{\text{EOR}})} \left[ 1 - \left( \frac{f_{\text{o4}}}{f_{\text{opeak}}} \right)^{1 - b_{\text{EOR}}} \right] \quad (21)$$

where  $N_{p4D}$  is the dimensionless final cumulative recovery.  $N_{p4D}$  is sometimes referred to as the recovery factor.

Equation (21) can be solved for the peak oil cut,  $f_{\text{opeak}}$ , if the remaining parameters in the equation are known or can be estimated. This equation can easily be solved using an iterative technique, such as Newton's method. Once  $f_{\text{opeak}}$  is known, then the dimensionless decline-rate constant can be determined using Eq. (20). Then, the decline-rate constant,  $D_{\text{iEOR}}$ , can be determined using Eq. (12).

Equation (21) is a central part of the solution procedure.

**Summary of Model Parameters.** The key model parameters are:  $\Delta t_2$ ,  $\Delta t_3$ ,  $\Delta t_4$ ,  $q_{\text{peak}}$ ,  $q_2$ ,  $D_{\text{iEOR}}$ ,  $b_{\text{EOR}}$ ,  $D_{\text{iWF}}$ , and  $b_{\text{WF}}$ . The remaining model parameters ( $t_{\text{iWF}}$ ,  $q_{\text{iWF}}$ , and  $t_1$ ) are either known or arbitrarily selected. In the following section, we outline the procedure to estimate the parameters.

### **Estimating Model Parameters**

We use different approaches to estimate the model parameters. The parameters  $\Delta t_2$ ,  $\Delta t_3$ ,  $\Delta t_4$ , and  $b_{\text{EOR}}$  are estimated using empirical correlations or guidelines. The guidelines are based on production trends from actual miscible floods. See Appendix C. The parameters  $D_{\text{iWF}}$ ,  $b_{\text{WF}}$ , and  $q_2$  are estimated from a decline-curve analysis of the preceding waterflood. The model parameters  $q_{\text{peak}}$  and  $D_{\text{iEOR}}$  are estimated based on material balance. The following discusses the procedures to estimate each parameter.

**Parameters  $b_{\text{WF}}$ ,  $D_{\text{iWF}}$ , and  $q_2$ .** The constants  $b_{\text{WF}}$  and  $D_{\text{iWF}}$  are determined from a conventional decline-curve analysis of the reservoir's waterflood rate history. This step obviously assumes that oil-rate data from the waterflood is available. Techniques to apply decline curves will not be reviewed here.

Once  $b_{\text{WF}}$  and  $D_{\text{iWF}}$  are determined,  $q_2(t_2)$  can then be determined from Eq. (3) once  $\Delta t_2$  is estimated. The method to estimate  $t_2$  is discussed momentarily.

In many instances, the oil-rate history for the miscible flood will be insensitive to the values of  $D_{\text{iWF}}$  and  $b_{\text{WF}}$  because the time difference  $t_2 - t_1$  is negligible compared to the overall flood life and because  $q_1$  and  $q_2$  are small. If this applies, curve-fitting the waterflood rate history to determine  $D_{\text{iWF}}$  and  $b_{\text{WF}}$  is unnecessary. Instead, setting  $t_{\text{iWF}} = t_1$  and  $q_{\text{iWF}} = q_1$  and adopting any reasonable values for  $D_{\text{iWF}}$  and  $b_{\text{WF}}$ , such as  $b_{\text{WF}} = 0$

and  $D_{iWF} = 30\%/year$  is quite acceptable. If this simplification is adopted, then the future incremental oil recovery predicted by the decline curve is not possible.

**Peak Oil-Rate Time,  $\Delta t_3$ .**  $\Delta t_3$  is the elapsed time from the start of solvent injection until the peak oil rate. This time difference generally varies between 1 and 6 years. Appendix C shows that  $\Delta t_3$  correlates well with the time constant  $V_p/Q_T$ ,

$$\Delta t_3 = 0.295 \left( \frac{V_p}{Q_T} \right) - 0.337 \quad 4.5 \text{ yrs} < V_p/Q_T < 20 \text{ yrs} \quad (22)$$

where  $\Delta t_3$  and  $V_p/Q_T$  are expressed in years. The appendix shows a plot of  $\Delta t_3$  versus  $V_p/Q_T$ . This equation yields a standard error of 0.17 years (2 months) and an average error of 4.2%. Equation (22) is a convenient means to quickly estimate  $\Delta t_3$ .

As discussed in Appendix C, Eq. (22) implies that the injected fluid volume—expressed in pore volume units—effectively determines  $\Delta t_3$ .

The peak rate occurs at approximately  $\Delta t_{D3} \approx 0.26$  pore volumes of fluid injected (PVI). The variable  $\Delta t_{D3}$  is defined as the PVI at the peak rate. This can be used as an alternative means to approximate  $\Delta t_3$ . Accordingly,  $\Delta t_3$  is

$$\Delta t_3 \approx 0.26 \left( \frac{V_p}{Q_T} \right) \quad (23)$$

where consistent units are assumed. Appendix C discusses the effect of the  $\Delta t_{D3}$  on the oil rate history. Equation. (23) is an acceptable approximation for the cases reviewed.

**Flood Life,  $\Delta t_4$ .** The time difference  $\Delta t_4$  is the flood life. The dimensional flood life varies between approximately 8 and 27 years.

Appendix C shows that  $\Delta t_4$  also correlates with the time constant according to

$$\Delta t_4 = 1.07 \left( \frac{V_p}{Q_T} \right) + 4.11 \quad 4.5 \text{ yrs} < V_p/Q_T < 20 \text{ yrs} \quad (24)$$

where  $\Delta t_4$  and  $V_p/Q_T$  are expressed in years. Appendix C shows that this equation yields a standard error of 0.91 years (11 months) and an average error of 4%. Since the time constant is invariably known, this equation gives a convenient means to quickly estimate  $\Delta t_4$ .

In terms of pore volumes of fluid injected, the flood life varies between approximately 1.25 and 1.95 PVI, i.e.,  $1.25 < \Delta t_{D4} < 1.95$ , where  $\Delta t_{D4}$  represents the dimensionless flood

life. Selecting  $\Delta t_4$  based on an average value  $\Delta t_{D4} = 1.5$  often yields reasonable results. Appendix C discusses this approximation, including its error, in greater detail.

The dimensionless flood life predicted by Eq. (24) is based on field data from U.S. onshore tertiary CO<sub>2</sub> floods. Since the expense of offshore operations is greater than onshore operations, the offshore operations will likely terminate before onshore operations, all other things equal. Thus, offshore operations may terminate at dimensionless flood life nearer to 1.25 than 1.95 PVI. The effect of operating costs on the economic limit and profitability is an economic issue and is ultimately investigated by coupling the rate model (using an approximate dimensionless flood life, e.g., 1.5 PVI) with a cash-flow projection.

The dimensionless flood life predicted by Eq. (24) is very similar to what is observed for waterfloods. For instance, Guerrero and Earlougher (1961) observed that waterflood life usually ranges between 1.25 and 1.7 PVI.

The range of scaled rates for miscible flooding approximately agrees with the range in waterflooding. Several investigators (Riley, 1964; Guerrero and Earlougher, 1961; and Bush and Helander, 1968), for instance, have reported that the scaled rate for a waterflood usually falls between 0.10 and 0.30 PVI/year, a surprisingly narrow range. The narrow range probably occurs because of economics. Rates below the lower limit usually do not occur because they are uneconomic. Rates greater than the upper limit don't occur because they permit larger well spacing and lower drilling expenditures. Because the range for waterflooding is relatively narrow, Willhite (1986) simply recommends using a generic value of 0.28 PVI/year when only approximate estimates are required. The preceding remarks may be useful to develop quick estimates of the time constant for miscible-flood scoping studies.

**Oil Bank Breakthrough Time,  $\Delta t_2$ .** The time difference  $\Delta t_2$  is the elapsed time from the start of solvent injection until oil bank breakthrough (BT).  $\Delta t_2$  is very short—between 1 and 3 months, or  $1 \text{ month} < \Delta t_2 < 3 \text{ months}$ .

This range implies a very quick oil response to solvent injection. Because  $\Delta t_2$  is very short, its effect on recovery is minor. Because its range is narrow, selecting any value within the range is acceptable. Once  $\Delta t_2$  is determined,  $t_2$  is determined from  $t_2 = \Delta t_2 + t_1$ .

In terms of the pore volumes of fluid injected, the range of oil bank breakthrough times is  $1 < \Delta t_{D2} < 4\%$ .

The preceding guidelines have been validated for well spacing greater than 10 acres. Therefore, they should be used carefully for well spacing less than 10 acres. Because the well spacing in most commercial projects greater than 10 acres, this is not a serious limitation. See Appendix C for a brief discussion of the performance of small pilot tests.

**Decline Exponent,  $b_{EOR}$ .** Based on our analysis of field data, we have observed that  $0 < b_{EOR} < 0.3$ .

Recall,  $b_{\text{EOR}} = 0$  is an exponential decline. Many solvent floods approach or fit an exponential decline. The difference between  $b_{\text{EOR}} = 0$  and  $b_{\text{EOR}} = 0.3$  on the rate history is small. Thus, assuming an exponential decline is not a poor assumption. The average value of  $b_{\text{EOR}}$  for commercial floods was 0.20. Thus, selecting  $b_{\text{EOR}} = 0.2$  is reasonable

The effect of increasing  $b_{\text{EOR}}$  is to increase  $q_{\text{peak}}$  and  $D_{\text{iEOR}}$ .

**Peak Oil rate,  $q_{\text{peak}}$ .** The peak oil rate  $q_{\text{peak}}$  is an important parameter affecting the recovery and controlling the shape of the rate history. The dimensionless peak oil cut,  $f_{\text{opeak}}$ , effectively describes  $q_{\text{peak}}$ .  $f_{\text{opeak}}$  varies between 7 and 31% for successful solvent floods, including pilots. For commercial floods, the range is narrower and lower, typically between 7 and 20%.

These ranges are not drastically smaller than for waterfloods. Bush and Helander (1968) noted that the 51% of the waterfloods experienced a peak oil rate between 12 and 31%, where the peak rate is expressed as a fraction of the water injection rate. The average for all waterfloods was 22%.

The peak oil rate is estimated using Eq. (21), the produced oil mass balance equation. This equation is first solved for  $f_{\text{opeak}}$ , and then  $q_{\text{peak}}$  is determined using Eq. (13). This approach assumes all the remaining parameters in Eq. (21) can be estimated, including the recovery factor. The recovery  $E_R$  factor is normally estimated as described in Appendix D. All of the remaining parameters can usually be estimated. For instance,  $f_{\text{o4}}$ , the oil cut at the economic limit, depends on economic factors; it typically varies between 1 and 4%.

Our approach to use material balance to estimate the peak oil rate is very similar to Willhite's (1986) approach in applying the Bush-Helander model to waterflood. Willhite showed that this approach yielded reasonable estimates of the peak rate.

**Decline-Rate Constant,  $D_{\text{iEOR}}$ .** The decline-rate constant  $D_{\text{iEOR}}$  is determined from Eqs. (20) and (12). Equation (20) is first used to determine the dimensionless decline-rate constant  $D_D$ . This equation is a function of the peak rate; thus, the peak rate must first be determined before using this equation. Then, Eq. (12) is used to compute  $D_{\text{iEOR}}$ .

$D_{\text{iEOR}}$  often falls between 15 and 40% per year. This range roughly agrees with the range observed for waterfloods. For instance, Bush and Helander (1968) observed that 70% of studied waterfloods experienced a decline-rate constant between 20 and 55% per year.

**Summary.** In summary,  $b_{\text{WF}}$ ,  $D_{\text{iWF}}$ ,  $q_{\text{iWF}}$ , and  $t_{\text{iWF}}$  are determined from a decline curve analysis of the preceding waterflood. The parameters  $\Delta t_2$ ,  $\Delta t_3$ ,  $\Delta t_4$ , and  $b_{\text{EOR}}$  are determined from empirical guidelines. The parameter  $q_2(\Delta t_2)$  is determined from a decline curve analysis of the waterflood after  $\Delta t_2$  is determined. The parameters  $q_{\text{peak}}$  and  $D_{\text{iEOR}}$  are determined from Eq. (21), a mass balance on the produced oil.

For a quick approximation, reasonable rate predictions can often be obtained by simply assuming  $\Delta t_{D2} = 0.02$ ,  $\Delta t_{D3} = 0.26$ ,  $\Delta t_{D4} = 1.50$ ,  $b_{EOR} = 0.2$  and then computing  $\Delta t_2$ ,  $\Delta t_3$ , and  $\Delta t_4$  from Eqs. (16), (17), and (19). See Appendix C for a greater discussion of this approximation.

### Model Applications

This section presents the results of three model applications: (1) the Twofreds CO<sub>2</sub> flood, (2) the Lost Soldier CO<sub>2</sub> flood, and (3) the Wertz CO<sub>2</sub> flood.

**Example 1: Twofreds CO<sub>2</sub> Flood.** The Twofreds (Delaware) field is located in west Texas, USA. Discovered in 1957, the field was produced under pressure depletion (10.4% estimated ultimate recovery) until 1963, and then under waterflood until February 1974. Then, continuous CO<sub>2</sub> injection began on the east side of the field. Eventually, the CO<sub>2</sub> was chased with alternate injection of exhaust gas (84% nitrogen) and water. The Twofreds project was the first field-scale tertiary CO<sub>2</sub> flood in a sandstone reservoir in Texas. The field was owned by HNG Fossil Fuels Co, Transpetco Engineering of the Southwest, and Murphy Oil Co.

The OOIP on the east side of field was 15.4 MM STB. The producing oil cut before CO<sub>2</sub> injection was about 1%. Within 2-4 months after CO<sub>2</sub> injection, the oil rate began to increase. The oil cut peaked at about 17.7% after six years. The operators reported a cumulative recovery of about 15.8% of the OOIP through June 1, 1993.

Figure 5 shows the oil rate history on semi-log coordinates. The gray region is the waterflood response; the green region denotes the CO<sub>2</sub> flood.

Figure 5. East side Twofreds production history, 1966-1993.

Table 7. Model parameters for applications.

Parameter	Value		
	Twofreds	Lost Soldier	Wertz
OOIP, MMSTB	15.4	240	172
Pore volume, MMRB	33.7	299	222
Injection rate, RB/day	4,322	101,800	136,000
Initial formation vol. factor, RB/STB	1.18	1.12	1.16
Initial water saturation, %	46.2	10	10
$E_R$ , %	17.2	11.2	10.1
Terminal oil cut, %	1	2.3	1.3
$\Delta t_{D2}$	0.025	0.02	0.03
$\Delta t_{D3}$	0.28	0.24	0.24
$\Delta t_{D4}$	1.25	1.7	1.95
$\Delta t_2$ , mo.	6	1.9	1.6.
$\Delta t_3$ , yrs	6.0	2.0	1.0
$\Delta t_4$ , yrs	27.9	12.7	8.9
$t_{iWF}$	1/1/1969	1/1/1988	1/1/1985
$q_{iWF}$ , STB/day	450	2900	6200
$b_{WF}$	0.10	0.50	0.01
$D_{iWF}$ , %/year	70	40	30
$b_{iEOR}$	0.30	0.20	0.10

Table 7 summarizes the model parameters. The yellow curve in Fig. 5 shows the predicted rate history. The model yields a good match of the actual history.

The operators reported an actual recovery of 15.8% OOIP through June 1, 1993. The model predicted a recovery of 16.1%.

Carbon dioxide injection into the west side of Twofreds did not begin until 1980. This example shows that the EOR rate model can effectively model cases where different areas of a field are developed at different times. The only requirement, however, is that the model must be applied sequentially rather than globally.

**Example 2: Lost Soldier CO<sub>2</sub> Flood.** The Lost Soldier Tensleep reservoir is located in Wyoming, USA. The reservoir was discovered in 1930. Primary production continued until 1962 when peripheral water injection began. Pattern waterflooding began in 1976. Alternate CO<sub>2</sub> and water injection began in July, 1989. The flood was operated by Amoco Production Co.

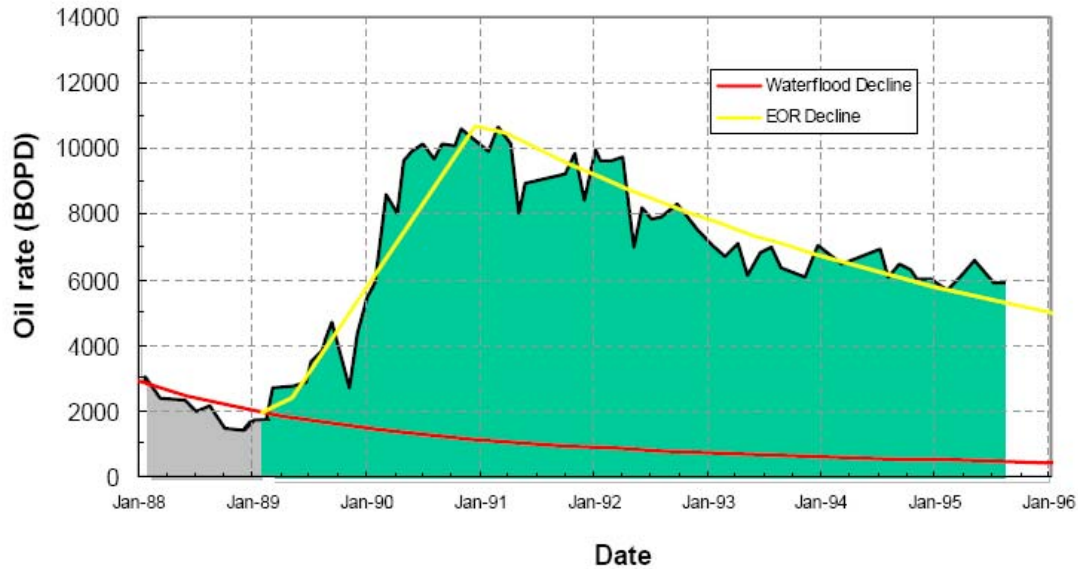

Figure 6. Lost Soldier production history, 1988-1996.

The OOIP at Lost Soldier Tensleep was 240 MM STB. The producing oil cut before CO<sub>2</sub> injection was approximately 2.5%. Oil bank breakthrough occurred within a few months. A peak oil cut of about 11% was realized after about 23 months. The operators reported an incremental oil recovery of 5.7% through January 1, 1996. They projected an ultimate cumulative recovery of 11.2%.

Figure 6 shows the oil rate history on Cartesian coordinates. The gray region denotes the waterflood; the green region the CO<sub>2</sub> flood. The waterflood was projected to recovery an additional 1% OOIP between the time of CO<sub>2</sub> injection and termination.

Table 7 summarizes the model parameters. The yellow curve in Fig. 6 shows the predicted rate history. The model yields a good match of the actual rate history.

The operators estimated an ultimate cumulative recovery of 11.2% OOIP. The model predicted an ultimate cumulative recovery of 10.9%.

**Example 3: Wertz CO<sub>2</sub> Flood.** The Wertz Tensleep reservoir is located in Wyoming, USA. The reservoir was discovered in 1936. Primary production was from a combination of fluid expansion and water influx. A pilot waterflood was carried out in 1978, and pattern waterflood was installed field wide in 1980. Waterflood performance was enhanced with infill drilling between 1982 and 1986. Alternate CO<sub>2</sub> and water injection began in November, 1986. The flood was operated by Amoco Production Co.

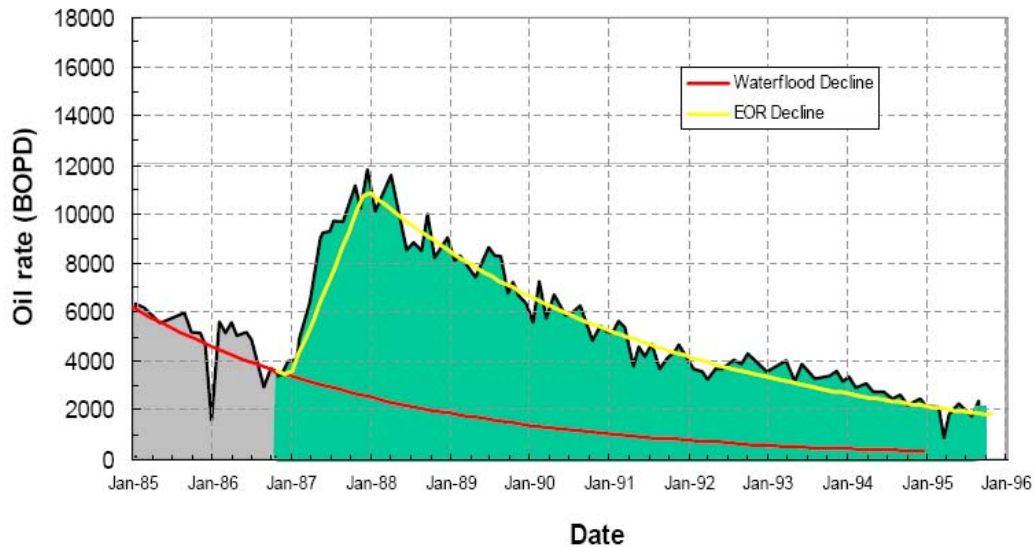

Figure 7. Wertz oil rate history, 1985-1996.

The OOIP at Wertz Tensleep was 172 MM STB. The producing oil cut prior to CO<sub>2</sub> injection was approximately 3.3%. Oil bank breakthrough occurred within a few months. A peak oil cut of about 10.2% was realized after about 13 months. The operators reported a cumulative recovery of 10.1% through January 1, 1996. The producing oil cut was less than 2%.

Figure 7 shows the oil rate history on Cartesian coordinates. The gray region denotes the waterflood; the green region the CO<sub>2</sub> flood. The red curve shows the projected waterflood decline. The waterflood was projected to recovery an additional 2.4% OOIP between the time of CO<sub>2</sub> injection and termination.

Table 7 summarizes the model parameters. The yellow curve in Fig. 7 shows the predicted rate history. The model matches the actual rate history.

The operators reported a cumulative recovery of 10.1% OOIP on Jan. 1, 1996. The model predicted a cumulative recovery of 10.3%.

**Conclusions.** The preceding examples show excellent agreement between model and actual results. Similar agreement was noted in the other commercial field cases (West Sussex, SACROC 4PA, and SACROC 17PA). These cases are not shown for the sake of brevity.

The results in the preceding examples are not a stringent test of the model inasmuch as its correlations were based on the data from these cases. The model results for the last three cases, however, are a more severe test of the model inasmuch as none of the field data

from these cases was used to develop the model correlations. Thus, these latter cases truly represent model predictions.

The West Sussex results are an especially severe test of the model because its rate response was very unusual in two respects. First, its peak oil cut was 31%; substantially greater than the peak oil cut for all the other commercial cases, which varied between 6 and 17%. Second, its decline rate constant (135% per year) was much larger than that for the other cases. Despite these differences, the rate model still matched this case very well.

The repeated success of the model helps validate it. The success is largely attributed to the accuracy of the  $\Delta t_3$  and  $\Delta t_4$  correlations.

### ***Model Limitations***

The model proposed here is a reasonable approach to empirically estimate the oil rate history of a tertiary miscible flood. It is similar to the Bush-Helander model for waterflooding. We have illustrated the model's ability to match and predict the oil rate of tertiary miscible floods. Our success is reminiscent of Willhite's (1986) in applying the Bush-Helander model. Though we have enjoyed success with the model, we have encountered and do recognize certain limitations.

First, the correlations used to estimate model parameters  $\Delta t_3$  and  $\Delta t_4$ —two very important parameters—are based on only six or seven field cases. On one hand, this is not very many field cases. On the other hand, the existing field data spans the entire expected range of time constants and the correlations yield very realistic predictions. Also, based on physical reasoning and our experience, we do not expect for  $\Delta t_{D3}$  and  $\Delta t_{D4}$  to fall outside of the range of existing data for new data. For example, we do not expect to find many solvent floods whose life is less than 1.25 or greater than 1.95 PVI. Nevertheless, the lack of data represents a limitation and we believe testing against more data is required.

Second, the model implicitly assumes a constant injection rate. This assumption is reasonable for many, but not all miscible floods. Some floods, such as Rangely, experience injectivity losses. This dramatic change has serious consequences on the oil rate. The current model cannot adequately treat this group of floods. The model will over-accelerate recovery and will over-estimate the producing oil rate. To treat these cases, the model must be modified for variable injection rates. It is questionable, however, whether this modification is really needed because injectivity is not reliably predictable.

Third, the model assumes the entire field is instantaneously converted to miscible flooding. In reality, a staggered development is sometimes implemented. In the Denver Unit of the Wasson field, for example, three very large portions of the unit were converted over a period of more than 8 years. The net effect of a staggered development relative to a single-stage development is to obviously expand the recovery period and diminish the peak oil rate.

***Summary and Conclusions***

We have successfully developed a non-simulation-based model to predict the rate history of tertiary solvent floods. The model is designed for scoping studies. The model is empirical and is based on hyperbolic decline curves and material balance. The model has been shown to closely match and predict the rate history of solvent floods. The model requires only minimal reservoir data to apply; namely, estimates of the OOIP, pore volume, cumulative EOR, injection rate, initial oil formation volume factor, and initial water saturation. Based on only this data, the model will predict the oil-rate history and cumulative recovery curve. The model is ideally suited for spreadsheet calculation and can be easily incorporated into existing cash-flow models.

## SCREENING CRITERIA

Table 8 shows a summary of miscible EOR screening criteria offered by several investigators (Brashear and Kuuskraa, 1978; Goodlett, et al., 1986; Taber, et al. 1997; Klins, 1984; Taber, and Martin, 1983). This table was assembled from an analysis of papers from the literature search. Screening criteria include variables such as depth, oil viscosity, oil gravity, oil saturation prior to flooding, operating pressure, oil composition, and pay thickness. Some investigators consider criteria for miscible EOR regardless of process; other investigators adopt different criteria for different processes within miscible EOR. For instance, Goodlett, et al. (1986) give separate criteria for hydrocarbon, nitrogen or flue gas, or carbon dioxide miscible projects.

Though most investigators ignore a criterion regarding pressure, it is implied that the reservoir pressure must meet or exceed the minimum miscibility pressure if miscibility is to be attained. This criterion is sometimes implied through the depth criterion.

Though these criteria are informative, they may be misleading. The criteria limits may be very different from industry average values, where the latter is defined as the average value for past and present projects. Taber et al. (1997) addressed this problem and offered an interesting set of criteria that included average parameter values. For example, most sets of criteria dictate a maximum oil viscosity of between 10 to 20 cp. Taber et al. in contrast, added that the average oil viscosity for past and present projects was between 0.2 and 1.5 cp. This example shows that the screening criteria may be so coarse that they do not accurately reflect what is needed for a successful project.

Appendix E includes a summary of screening criteria for other EOR categories, such as chemical flooding. Copies of selected pages and tables from cited literature are reproduced.

Table 8. Miscible EOR Screening Criteria

Parameter	Brashear & Kuuskraa	Goodlett, et al.		
		HC Miscible	N <sub>2</sub> , flue gas	CO <sub>2</sub>

## NOMENCLATURE

BPD	Barrels per day
$B_o$	Oil formation volume factor
$B_s$	Solvent (gas) formation volume factor
$B_w$	Water formation volume factor
$b$	Decline exponent (Arps exponent)
$D$	Decline rate
$D_D$	Dimensionless decline rate
EOR	Enhanced oil recovery
$E_R$	Efficiency or recovery factor
$f_o$	Oil cut
MSCF	Thousands of standard cubic feet
MSCFPD	Thousands of standard cubic feet per day
$N_p$	Cumulative produced oil
$N$	Original oil inplace
OOIP	Original oil inplace
$Q$	Injection rate
$Q_T$	Total injection rate
$q$	Production rate
RB	Reservoir barrels
$S_w$	Water saturation
SCF	Standard cubic feet
STB	Stock-tank barrels
$t$	Time
$V_p$	Pore volume

### ***Greek Symbols***

$\Delta$	Operator that refers to discrete change
----------	---

### ***Subscripts***

peak	Peak rate
$i$	Initial
WF	Waterflood
EOR	Enhanced oil recovery process
$D$	Dimensionless
$w$	Water
$o$	Oil
$s$	Solvent

## CONVERSION FACTORS

1 m <sup>3</sup>	=	35.3 ft <sup>3</sup>
1 m <sup>3</sup>	=	6.29 bbls
1 km <sup>2</sup>	=	247.1 acres
1 km <sup>2</sup>	=	100 hectares
1 atm	=	14.7 psia
6.896 MPa	=	1000 psia
1 m	=	3.28 ft
(°F)	=	1.8(°C) + 32

## APPENDIX A: PAPER INVENTORY

The following is a listing of the paper inventory. More information about the papers can be found in Excel file "EOR\_Paper\_Inventory" on the accompanying Compact Disc (CD). The papers are ordered according to SPE number, from lowest to highest. This order approximately follows a chronological order, from oldest to youngest.

We began with a brief review of the Danish resource base. To familiarize ourselves with the resource base and reservoir operations, we also reviewed some papers from the SPE library. Some of these papers are listed below and included in the paper archive.

	SPE Paper No.	Title	Year
1	43-PA	Ten Years of Miscible Displacement in Block 31 Field	1961
2	66-MS	CARBONATED WATERFLOOD RESULTS--TEXAS AND OKLAHOMA	
3	256-MS	Processing of Geological and Engineering Data Multipay Fields for Evaluation	
4	333-MS	Case Histories of Carbonated Waterfloods in Dewey-Bartlesville Field	
5	341-PA	Small Propane Slug Proving Success in Slaughter Field Lease	1963
6	625-PA	LPG-Gas Injection Recovery Process Burkett Unit, Greenwood County, Kansas	1963
7	626-PA	Performance of a Miscible Flood with Alternate Gas-Water Displacement	1964
8	713-G	A Field Test of the Gas-Driven Liquid Propane Method of Oil Recovery	1957
9	824-PA	Meadow Creek Unit Lakota "B" Combination Water-Miscible Flood	1964
10	945-PA	An Efficient Gas Displacement Project Raleigh Field, Mississippi	1963
11	1126-PA	Performance of Domes Unit Carbonated Waterflood - First Stage	
12	1260-G	Pilot Propane Project Completed in West Texas Reef	1959
13	1884-PA	Performance of Seeligson Zone 20B-07 Enriched-Gas-Drive Project	1967
14	1907-MS	Success of Flue Gas Program At Neale Field	1967
15	2303-MS	Waterflood Performance Of a Shallow Channel Sandstone Reservoir Burkett Pool, Coleman County, Texas	1968
16	2418-PA	A Current Appraisal of Field Miscible Slug Projects	1970
17	2644-PA	Ante Creek - A Miscible Flood Using Separator Gas and Water Injection	1970
18	2837-PA	Case History of the University Block 9 (Wolfcamp) FieldA Gas-Water Injection Secondary Recovery Project	1970
19	2845-PA	Performance of a Propane Slug Pilot in a Watered-Out SandSouth Ward Field	1970
20	2930-PA	Prediction of Recovery in Unstable Miscible Flooding	
21	3103-PA	Carbon Dioxide Test at the Mead-Strawn Field	1971
22	3441-PA	Steam Distillation Drive-Brea Field, California	
23	3487-MS	High Pressure Miscible Gas Displacement Project, Bridger Lake Unit, Summit County	1971
24	3773-PA	Advanced Technology Improves Recovery at Fairway	1973
25	3774-PA	Propane-Gas-Water Miscible Floods In Watered-Out Areas of the Adena Field, Colorado	1972
26	3775-MS	Tertiary Miscible Flood in Phegley Unit, Washington County, Colorado	1972
27	4083-PA	Evaluation and Design of a CO2 Miscible Flood Project-SACROC Unit, Kelly-Snyder Field	1973
28	4600-PA	Performance of a Miscible Flood in the Bear Lake Cardium Unit, Pembina Field, Alberta, Canada	1975
29	4764-MS	Fosterton Northwest - A Tertiary Combustion Case History	
30	5080-PA	Miscible Flood Performance of the Intisar "D" Field, Libyan Arab Republic	1975

	SPE		
	<u>Paper No.</u>	<u>Title</u>	<u>Year</u>
31	5536-PA	Reservoir Description by Simulation at SACROC - A Case History	1976
32	5539-MS	Reservoir Engineering Design of a Tertiary Miscible Gas Drive Pilot Project	1975
33	5560-PA	Status of CO2 and Hydrocarbon Miscible Oil Recovery Methods	1976
34	5821-PA	A Study of Fireflood Field Projects (includes associated paper 6504)	
35	5826-PA	Enriched-Gas Miscible Flooding: A Case History of the Levelland Unit Secondary Miscible Project	1977
36	5826-PA	Enriched-Gas Miscible Flooding: A Case History of the Levelland Unit Secondary Miscible Project	
37	5893-MS	Non-Thermal Heavy Oil Recovery Methods	
38	6117-PA	An Evaluation of Miscible CO2 Flooding in Waterflooded Sandstone Reservoirs	1977
39	6140-PA	Pool Description and Performance Analysis Leads to Understanding Golden Spike's Miscible Flood	1977
40	6350-PA	The Potential and Economics of Enhanced Oil Recovery	
41	6388-MS	A Review of the Willard (San Andres) Unit CO2 Injection Project	1977
42	6390-PA	North Cross (Devonian) Unit CO2 Flood - Review of Flood Performance and Numerical Simulation Model	1978
43	6391-MS	Corrosion and Operational Problems, CO2 Project, Sacroc Unit	1977
44	6624-MS	APPRAISAL OF MICELLAR FLOODING, CARBON DIOXIDE AND SURFACTANT FLOODING PROJECTS	
45	6626-MS	DEVELOPMENT OF A PILOT CARBON DIOXIDE FLOOD IN THE ROCK CREEK- BIG INJUN FIELD, ROANE COUNTY, WEST VIRGINIA	1977
46	6747-MS	A CO2 TERTIARY RECOVERY PILOT LITTLE CREEK FIELD, MISSISSIPPI	1977
47	6974-MS	ENHANCED OIL RECOVERY TECHNIQUES - STATE OF THE ART REVIEW	
48	7049-MS	USE OF TIME-LAPSE LOGGING TECHNIQUES IN EVALUATING THE WILLARD UNIT CO2 FLOOD MINI-TEST	1978
49	7051-MS	A METHOD FOR PROJECTING FULL-SCALE PERFORMANCE OF CO2 FLOODING IN THE WILLARD UNIT	1978
50	7090-MS	SACROC TERTIARY CO2 PILOT PROJECT	1978
51	7091-PA	Performance Review of a Large-Scale CO2-WAG Enhanced Recovery Project, SACROC Unit Kelly-Snyder Field	1979
52	7553-MS	RESERVOIR STUDY OF THE CAMP SAND, HAYNESVILLE FIELD, LOUISIANA	1978
53	8200-PA	History Match Analysis of the Little Creek CO2 Pilot Test	1980
54	8382-MS	TWOFREDS FIELD A TERTIARY OIL RECOVERY PROJECT	1979
55	8410-MS	DESIGN AND OPERATION OF THE LEVELLAND UNIT CO2 INJECTION FACILITY	1979
56	8740-MS	GRANNY'S CREEK CO2 INJECTION PROJECT, CLAY COUNTY, WEST VIRGINIA	1979
57	8830-PA	Slaughter Estate Unit CO2 Pilot - Surface and Downhole Equipment Construction and Operation in the Presence of H2S	1981
58	8831-MS	DESIGN AND IMPLEMENTATION OF A LEVELLAND UNIT CO2 TERTIARY PILOT	1980
59	8832-MS	REVIEW AND ANALYSIS OF PAST AND ONGOING CARBON DIOXIDE INJECTION FIELD TESTS	1980
60	8897-PA	Carbon Dioxide Well Stimulation: Part 2 -- Design of Aminoil's North Bolsa Strip Project (includes associated papers 11928 and 12234 )	1982

	SPE Paper No.	Title	Year
61	9415-PA	Unique Enhanced Oil and Gas Recovery for Very High-Pressure Wilcox Sands Uses Cryogenic Nitrogen and Methane Mixture	1980
62	9430-PA	A Single CO2 Injection Well Minitest in a Low-Permeability Carbonate Reservoir	1980
63	9430-PA	A Single CO2 Injection Well Minitest in a Low-Permeability Carbonate Reservoir	1982
64	9719-PA	Response of North Cowden and Goldsmith Crudes to Carbon Dioxide Slugs Pushed by Nitrogen	1984
65	9786-MS	UTILIZATION OF COMPOSITION OBSERVATION WELLS IN A WEST TEXAS CO2 PILOT FLOOD	1981
66	9796-PA	Slaughter Estate Unit Tertiary Pilot Performance	1981
67	9798-MS	SAN ANDRES RESERVOIR PRESSURE CORING PROJECT FOR ENHANCED OIL RECOVERY EVALUATION, BENNETT RANCH UNIT, WASSON FIELD, WEST TEXAS	
68	9805-PA	Planning a Tertiary Oil-Recovery Project for Jay/LEC Fields Unit	1983
69	9830-MS	APPRAISING FEASIBILITY OF TERTIARY RECOVERY WITH CARBON DIOXIDE	1982
70	9976-PA	Some Aspects of the Potential Application of Surfactants or CO2 as EOR Processes in North Sea Reservoirs	1982
71	9992-PA	Status of Miscible Displacement	1982
72	10026-MS	The Wizard Lake D-3A Pool Miscible Flood	1984
73	10159-MS	Analysis and Design of a Deep Reservoir, High Volume Nitrogen Injection Project in the R-1 Sand, Lake Barre Field	
74	10160-PA	Implementation of a Gravity-Stable Miscible CO2 Flood in the 8000 Foot Sand, Bay St. Elaine Field	
75	10245-PA	Review of Miscible Flood Performance, Intisar "D" Field, Socialist People's Libyan Arab Jamahiriya	1983
76	10292-PA	CO2 Flood Performance Evaluation for the Cornell Unit, Wasson San Andres Field	
77	10547-PA	Thistle Field Development	1983
78	10693-MS	CO2 Injection for Tertiary Oil Recovery, Granny's Creek Field, Clay County, West Virginia	1983
79	10693-MS	CO2 Injection for Tertiary Oil Recovery, Granny's Creek Field, Clay County, West Virginia	
80	10695-MS	Weeks Island "S" Sand Reservoir B Gravity Stable Miscible CO2 Displacement, Iberia Parish, Louisiana	
81	10696-PA	Enhanced Oil Recovery by CO2 Miscible Displacement in the Little Knife Field, Billings County, North Dakota	1984
82	10727-PA	Slaughter Estate Unit Tertiary Miscible Gas Pilot Reservoir Description	1984
83	10731-MS	Technical Feasibility of Chemical Flooding in California Reservoirs	1984
84	10935-MS	A New Dawn for CO2 EOR	1986
85	11129-MS	Numerical Simulation of a Gravity Stable, Miscible CO2 Injection Project in a West Texas Carbonate Reef	1986
86	11162-MS	Ten Years of Handling CO2 for SACROC Unit	1986
87	11303-PA	Valuation of Supplemental and Enhanced Oil Recovery Projects With Risk Analysis	1987
88	11305-MS	Should We Continue To Explore in the North Sea?	1985
89	11506-MS	Design and Evaluation of a Gravity-Stable, Miscible CO2-Solvent Flood, Bay St. Elaine Field	
90	11902-PA	Analysis of Nitrogen-Injection Projects to Develop Screening Guides and Offshore Design Criteria	1980

SPE		Title	Year

## **APPENDIX B: CATALOGUE OF MISCIBLE FLOOD OIL-RATE HISTORIES**

This appendix presents oil-rate histories for the following fields or units:

Rangely Weber Sand Unit  
Ford Geraldine Unit  
Wasson Denver Unit  
Wertz Tensleep  
Lost Soldier Tensleep  
Means San Andres Unit  
Slaughter Estate Unit  
Hanford San Andres  
Salt Creek  
Goldsmith Pilot  
Granny's Creek Pilot  
Maljamar Pilot  
Slaughter Estate Unit Pilot  
Dollarhide  
Sundown Slaughter Unit  
Twofreds  
West Sussex  
Seminole San Andres Unit  
Willard Unit, Wasson field  
SACROC Unit, Kelly-Snyder field, Four-Pattern Area  
SACROC Unit, Kelly-Snyder field, Seventeen-Pattern Area

## Field: Rangely Weber Sand Unit

### Key Papers

1. Attanucci, V., et al.: "WAG Process Optimization in the Rangely CO<sub>2</sub> Miscible Flood," SPE 26622, presented at the 1993 Annual Technical Conference and Exhibition, Houston, Tx (1993).
2. Masoner, L.O. and Wackowski, R.K.: Rangely Weber Sand Unit CO<sub>2</sub> Project Update: Decisions and Issues Facing a Maturing EOR Project," SPE 27756, presented at the 1994 Improved Oil Recovery Symposium, Tulsa, OK (1994).

### Key rate history plots:

## APPENDIX C: SUPPLEMENTAL EMPIRICAL CORRELATIONS

The EOR rate model requires estimating the following times:  $t_2$ ,  $t_3$ , and  $t_4$ . This appendix presents development of empirical methods to estimate these times. The correlations in this appendix are based on a statistical analysis of data from the database (Table 6).

The correlations are based on field data from the Twofreds, Wertz, Lost Soldier, and SEU fields. The data from the remaining fields in the database (West Sussex, SACROC 4PA, and SACROC 17PA) were not available when correlations were first prepared. We did not update the correlations because the additional data did not appreciably change them.

### **Model Parameter $\Delta t_3$**

The time  $t_3$  is date of the peak oil rate. The variable  $\Delta t_3$  is the elapsed time from the start of solvent injection until the peak oil rate.

$\Delta t_3$  usually falls between 1 and 6 years. We have observed that  $\Delta t_3$  correlates with the time constant  $V_p/Q_T$ . Physically, this ratio is the time to inject 1 pore volume of fluid into the reservoir. The inverse of the time constant,  $Q_T/V_p$ , is a scaled measure of the solvent flood's rate. Figure C1 shows a plot of  $\Delta t_3$  versus  $V_p/Q_T$ . As expected,  $\Delta t_3$  increases as  $V_p/Q_T$  increases and  $Q_T/V_p$  decreases. Physically, this relationship shows that the elapsed time to reach the peak oil rate increases as the scaled flood rate decreases. Figure C1 shows a linear relationship between  $\Delta t_3$  and  $V_p/Q_T$ . Linear regression yields the following relationship between  $\Delta t_3$  and  $V_p/Q_T$

$$\Delta t_3 = 0.295 \left( \frac{V_p}{Q_T} \right) - 0.337 \quad 4.5 \text{ yrs} < V_p/Q_T < 20 \text{ yrs} \quad (C1)$$

where  $\Delta t_3$  and  $V_p/Q_T$  are expressed in years. This equation has a standard error of 0.17 years (2 months) and an average error of 4.2%. Since the time constant is known for a solvent flood, this equation gives an effective way to estimate the time difference  $\Delta t_3$ .

Equation (C1) is fit to the data give by the black dots in Figure C1. These points correspond to field data from Twofreds, Wertz, and Lost Soldier (LS) fields. Later, data points for West Sussex, SACROC 4PA, and SACROC 17PA became available and were added (open circles), but the correlation was not updated because the trend did not appreciably change. The additional data constitute a confirmation of the correlation.

The time constant usually falls within a relatively narrow range. The time constants in Fig. C1, for example, vary between only 4.5 and 22 years/PVI. This range corresponds to a range of scaled rates between approximately 0.05 and 0.22 PVI/year. This range approximately agrees with the range for waterfloods. For instance, Riley (1964), Guerrero and Earlougher (1961), and Bush and Helander (1968) have observed that the scaled rate for most waterfloods generally falls between 0.10 and 0.30 PVI/year, a relatively narrow range. Willhite (1986) simply recommends assuming an average value of 0.29 PVI/year.

Figure C1. Time of peak oil rate ( $\Delta t_3$ ) versus time constant.

That the y-intercept in Fig. C1 nearly passes through the origin implies that the total injected fluid volume, expressed in pore volumes units at the peak time, is approximately constant, near 0.26 PVI. The variable  $\Delta t_{D3}$  is defined as the pore volumes of fluid injected at the peak rate. Thus,  $\Delta t_{D3} \approx 0.26$ . Equation. (C1) actually predicts that  $\Delta t_{D3}$  falls within a narrow range, between 0.24 and 0.28 PVI, i.e.,  $0.24 < \Delta t_{D3} < 0.28$ . This range be used an alternate means to estimate  $\Delta t_3$ . First, a value for  $\Delta t_{D3}$  within the range is selected; then, the corresponding value of  $\Delta t_3$  is computed. The field data gives an average  $\Delta t_{D3}$  value of 0.254. The effect of  $\Delta t_{D3}$  (within its range) on the resulting rate history is small. Thus, any value within the cited range is acceptable. Even values within the larger range  $0.20 < \Delta t_{D3} < 0.33$  have only a weak effect on the rate history. Relative to the base case of  $\Delta t_{D3} = 0.26$ , for instance, the average error in the yearly oil production over a 20-year flood life is less than 0.5% of the injection rate for  $\Delta t_{D3} = 0.20$  and less than 0.7% of the injection rate for  $\Delta t_{D3} = 0.33$ . These results are for a cumulative recovery of 10% and  $b_{EOR} = 0$ . These results illustrate relative insensitivity of the rate to  $\Delta t_{D3}$ . If we simply assume  $\Delta t_{D3} = 0.254$ , then the time difference  $\Delta t_3$  is then computed by solving Eq. (16)

$$\Delta t_3 = \frac{\Delta t_{D3} V_p}{Q_T} \approx \frac{0.254 V_p}{Q_T} \quad (C2)$$

where  $\Delta t_3$  and  $V_p/Q_T$  are expressed in years.

The correlation in Eq. (C1) and the guideline given above are valid if the well spacing is greater than 10 acres. For smaller well spacing, such as for pilot tests, solvent floods are usually much more efficient and the peak oil rate is delayed later than that predicted). In the case of the Slaughter Estate CO<sub>2</sub> pilot where the well spacing was only 3 acres, for example, the peak oil rate does not occur until 54% of a pore volume of fluid is injected, i.e.,  $\Delta t_{D3} = 0.54$ . The red data point in Figure C1 shows the data point for the SEU pilot.

Clearly, the data supporting Eqs. (C1) and (C2) is sparse. Additional data would be helpful. However, because the rate history is relatively insensitive to  $\Delta t_{D3}$ , acquiring more data is not critical.

Our findings are qualitatively similar to the results of Bush and Helander who studied waterflooding. They tried to determine the time of the peak oil rate for a waterflood following pressure depletion. They found that the time of the peak oil rate correlated with the time constant and corresponded to a relatively narrow range of dimensionless times. For their study of 86 waterfloods, for instance, they found that the peak oil rate occurred at an average of 0.33 pore volumes of water injected.

#### **Model Parameter $\Delta t_4$**

The time  $t_4$  is the termination date. The variable  $\Delta t_4$  is the elapsed time ( $t_4 - t_1$ ) from the start of solvent injection until termination. It represents the flood life.

$\Delta t_4$  is between 8 and 27 years—a rather wide range. However,  $\Delta t_4$  also correlates with the time constant  $V_p/Q_T$ . Figure C2 shows a plot of  $\Delta t_4$  versus  $V_p/Q_T$ . As expected,  $\Delta t_4$  increases as  $V_p/Q_T$  increases and  $Q_T/V_p$  decreases. Physically, this relationship shows that the flood life increases as the scaled flood rate decreases. The linear regression relationship between  $\Delta t_3$  and  $V_p/Q_T$  is

$$\Delta t_4 = 1.07 \left( \frac{V_p}{Q_T} \right) + 4.11 \quad 4.5 \text{ yrs} < V_p/Q_T < 20 \text{ yrs} \quad (C3)$$

where  $\Delta t_4$  and  $V_p/Q_T$  are in years. Equation (C3) a standard error of 0.91 years (11 months) and an average error of 4%. Since  $V_p/Q_T$  is usually known, Eq. (C3) is a way to estimate  $\Delta t_{D4}$ .

Equation (C3) predicts  $\Delta t_4$  is a sole function of the time constant. This is probably an oversimplification. Other factors, especially economic factors such as operating expenses, will also influence the flood life.

The flood life can also be described in terms of the pore volumes injected (PVI). The field data shows that the flood life ranges between 1.25 and 1.95 PVI.  $\Delta t_{D4}$  is a dimensionless flood life. The dimensionless life of a tertiary miscible flood is about the same as that of a waterflood. For instance, Guerrero and Earlougher (1961) observed that waterflood life usually ranges between 1.25 and 1.7 PVI.

The observed rate history is not overly sensitive to  $\Delta t_{D4}$  as long as an average value within its range is selected. In many cases, simply selecting  $\Delta t_4$  based on a value of  $\Delta t_{D4} = 1.5$  is often very reasonable. If this simplified guideline is accepted, then

$$\Delta t_4 = \frac{\Delta t_{D4} V_p}{Q_T} = \frac{1.5 V_p}{Q_T} \quad (C5)$$

where consistent units are assumed. For example, if  $V_p [=] \text{rm}^3$  and  $Q_T [=] \text{rm}^3/\text{day}$  ( $\text{rm}^3$  denotes reservoir  $\text{m}^3$ ), then  $\Delta t_4 [=]$  days. Relative to a base case of  $\Delta t_{D4} = 1.5$ , for instance, the average error in the yearly oil production over flood life (20 years) was only 0.83% of the injection rate for  $\Delta t_{D4} = 1.75$  and was only 0.98% of the injection rate for  $\Delta t_{D4} = 1.25$  PVI. This case assumed a cumulative recovery of 10% and  $b_{EOR} = 0$ . These results show that the error in simply assuming  $\Delta t_{D4} = 1.5$  PVI is reasonably small.

Figure C2. Flood life ( $\Delta t_4$ ) versus time constant.

**Model Parameter  $\Delta t_2$** 

The time  $t_2$  is date of the oil bank breakthrough. The time difference  $\Delta t_2 (= t_2 - t_1)$  is the time from the start of solvent injection until oil bank breakthrough.

$\Delta t_2$  is very short—usually between 1 and 3 months. Expressed as a percentage of the solvent flood's life (typically 8-27 years),  $\Delta t_2$  is relatively insignificant. Therefore, the specific choice of  $\Delta t_2$  within this range usually makes little difference.

Alternatively,  $\Delta t_2$  can be expressed terms of pore volumes of fluid injected,  $\Delta t_{D2}$ . Selecting any value within the range  $1 < \Delta t_{D2} < 4\%$  is acceptable and reasonable. This range is an alternative means to estimate  $\Delta t_2$ .

**Summary**

The rate model requires estimating three key time parameters:  $\Delta t_2$ ,  $\Delta t_3$ , and  $\Delta t_4$ . These parameters can be estimated from the time constant,  $V_p/Q_T$ , which is invariably known or can be estimated. The time parameters can also be estimated from their dimensionless counterparts:  $\Delta t_{D2}$ ,  $\Delta t_{D3}$ , and  $\Delta t_{D4}$ . The dimensionless times are observed to fall within a relatively narrow range:  $0.01 < \Delta t_{D2} < 0.04$ ,  $0.24 < \Delta t_{D3} < 0.28$ , and  $1.25 < \Delta t_{D4} < 1.95$ . Reasonably accurate predictions can be produced if one simply assumes  $\Delta t_{D2} = 0.02$ ,  $\Delta t_{D3} = 0.26$ , and  $\Delta t_{D4} = 1.5$ .

## APPENDIX D: ESTIMATING INCREMENTAL RECOVERY

The incremental recovery of successful commercial tertiary solvent floods typically ranges between 7 and 16% of the OOIP. The incremental recovery of tertiary pilot floods is often greater and can be as much as 20% of the OOIP.

Various methods are used to estimate recovery factors for screening purposes. This Appendix presents a brief mathematical derivation of some equations that can be used as a starting point for an evaluation.

Let us define the following variables:

$$\begin{aligned} N_{pWF} &= \text{cumulative oil volume recovered through waterflooding} \\ N_{pEOR} &= \text{cumulative oil volume recovered through EOR} \\ B_{oWF} &= \text{oil formation volume factor at the end of waterflooding} \\ B_{oEOR} &= \text{oil formation volume factor at the end of EOR} \end{aligned}$$

If the reservoir is initially undersaturated, then the initial oil saturation is  $(1-S_{wi})$ . The average oil saturation at the end of waterflooding is

$$S_{oWF} = \frac{(N - N_{pWF}) B_{oWF}}{V_p} \quad (D1)$$

where  $(N - N_{pWF})$  represents the oil remaining after waterflooding. If  $E_v$  is the volumetric efficiency of the EOR process and  $S_{om}$  is the remaining or residual oil saturation in the swept zone (see Figure D1), then oil remaining at the end of EOR is

$$N - N_{pEOR} = \frac{V_p}{B_{oEOR}} [S_{om} E_v + S_{oWF} (1 - E_v)] \quad (D2)$$

where the first term in the brackets accounts for the swept zone and second term accounts for the unswept zone.  $S_{om}$  is usually estimated from laboratory core tests or is a fitting parameter. The cumulative oil recovery during EOR is

$$N_p = N_{pEOR} - N_{pWF} \quad (D3)$$

Substituting Eq. (D1) into (D2), and then solving the resulting equation for  $N_{pEOR}$  and then substituting the result into Eq. (D3) gives

$$\frac{N_p}{N} = \left( 1 - \frac{N_{pWF}}{N} \right) \left[ 1 - (1 - E_v) \frac{B_{oWF}}{B_{oEOR}} \right] - \frac{B_{oi} S_{om}}{B_{oEOR} (1 - S_{wi})} E_v \quad (D4)$$

Figure D1. Swept and unswept areas during solvent flooding in a quarter 5-spot pattern.

where  $N_p/N$  is the cumulative recovery during solvent flooding expressed as a fraction of the OOIP, and we have used  $NB_{oi}/(1-S_{wi})$  to replace  $V_p$ . If  $B_{oWF} = B_{oEOR}$ , then this equation simplifies to

$$\frac{N_p}{N} = \left( 1 - \frac{N_{pWF}}{N} - \frac{B_{oi}S_{om}}{B_{oEOR}(1-S_{wi})} \right) E_v \quad (D5)$$

If  $B_{oEOR}$  is approximately equal to  $B_{oi}$ , then Eq. (D5) becomes

$$\frac{N_p}{N} = \left( 1 - \frac{N_{pWF}}{N} - \frac{S_{om}}{(1-S_{wi})} \right) E_v \quad (D6)$$

If  $\Delta N_{pWF}$  is the hypothetical oil recovery from continued waterflooding, then the fractional incremental oil recovery from solvent flooding is

$$\frac{\Delta N_p}{N} = \frac{N_p}{N} - \frac{\Delta N_{pWF}}{N} \quad (D7)$$

The following example illustrates the application of Eqs. (D6) and (D7).

**Example: Estimating the Incremental EOR for Slaughter Estate Unit CO<sub>2</sub> Pilot.**

Primary recovery and waterflooding recovered 9.4 and 29.9% of the OOIP, respectively, in the SEU pilot. Therefore,  $N_{pWF}/N = 39.3\%$ . Continued waterflooding was projected to recover an additional 11.2% of the OOIP. Therefore,  $\Delta N_{pWF}/N = 11.2\%$ . The initial water saturation was 9.1%. The operators reported  $S_{om} = 12\%$  from core tests. If the final areal and vertical sweep efficiencies are 90% and 70%, then  $E_v = 0.63$ . To compute the cumulative recovery during CO<sub>2</sub> flooding, we apply Eq. (D6):

$$\frac{N_p}{N} = \left( 1 - \frac{N_{pWF}}{N} - \frac{S_{om}}{(1 - S_{wi})} \right) E_v = \left( 1 - 0.393 - \frac{0.12}{(1 - 0.091)} \right) (0.63) = 30.0\%$$

To compute the incremental recovery, we apply Eq. (D7):

$$\frac{\Delta N_p}{N} = \frac{N_p}{N} - \frac{\Delta N_{pWF}}{N} = 0.30 - 0.112 = 18.8\%$$

These estimates agree closely with the actual values of 30.8 and 19.6%, respectively.

## APPENDIX E: CATALOGUE OF EOR SCREENING CRITERIA

This appendix presents sets of screening criteria gathered from the literature search. This appendix consists of actual pages copied from the references. For a more detailed discussion, the reader is referred to the reference. The screening criteria are for miscible, chemical, and thermal EOR.

### Screening Criteria

1. Brashear, J.P. and Kuuskraa, V.A.: The Potential and Economics of Enhanced Oil Recovery, J. Pet. Tech., SPE 06350, (Sept., 1978), 1231.

TABLE 1—CRITERIA FOR THE APPLICATION OF SELECTED EOR METHODS\*

Screening Parameters	Steam Drive	In-Situ Combustion	CO <sub>2</sub> Miscible	Micellar/Polymer	Improved Waterflood
Viscosity, cp at reservoir conditions	NC <sup>1</sup>	NC	<12	<20	<200

5. Rivas, O., Embid, S., and Bolivar, F.: "Ranking Reservoirs for Carbon Dioxide Flooding Processes," SPE 23641, SPE Advanced Technology Series, Vol. 2, No. 1 (1994).

Results obtained with the three simulators compare quite well and indicate that on the average, the best reservoir for carbon dioxide injection should have an oil gravity of 36 °API, a temperature of 150 °F, a permeability of 300 mD, an oil saturation at the start of the injection of 60 %, a reservoir pressure at the time of injection of around 200 psi over minimum miscibility pressure, a porosity of 20 %, a net sand thickness of 40 ft and a reservoir dip of 20 °.

Results of simulations studies indicate that the reservoir properties which most influence CO<sub>2</sub> flooding performance are API gravity, oil saturation and pressure. Reservoirs with an oil gravity around 37 °API, an oil saturation around 60 % and a pressure 1.3 the minimum miscibility pressure should be preferred for the process. A comparison of the simulators used here indicates that the semi-analytical predictive type model does a good job predicting CO<sub>2</sub> flooding performance, often in agreement with the fully compositional simulator.

<b>Parameter</b>	<b>Optimum</b>	<b>Worst (left)</b>	<b>Worst (right)</b>	<b>Weight</b>
Api Gravity	37	20	71	0.24

Table 3  
HYDROCARBON MISCIBLE FLOODING

Description

Hydrocarbon miscible flooding consists of injecting light hydrocarbons through the reservoir to form a miscible flood. Three different methods are used. One method uses about 5% PV slug of liquified petroleum gas (LPG) such as propane, followed by natural gas or gas and water. A second method, called Enriched (Condensing) Gas Drive, consists of injecting a 10-20% PV slug of natural gas that is enriched with ethane through hexane ( $C_2$  to  $C_6$ ), followed by lean gas (dry, mostly methane) and possibly water. The enriching components are transferred from the gas to the oil. The third method, called High Pressure (Vaporizing) Gas Drive, consists of injecting lean gas at high pressure to vaporize  $C_2 - C_6$  components from the crude oil being displaced.

Mechanisms

Hydrocarbon miscible flooding recovers crude oil by:

- generating miscibility (in the condensing and vaporizing gas drive)
- increasing the oil volume (swelling)
- decreasing the viscosity of the oil

TECHNICAL SCREENING GUIDES

Crude Oil

Gravity	> 35° API
Viscosity	< 10 cp
Composition	High percentage of light hydrocarbons ( $C_2 - C_7$ )

Reservoir

Oil Saturation	> 30% PV
Type of Formation	Sandstone or carbonate with a minimum of fractures and high permeability streaks
Net Thickness	Relatively thin unless formation is steeply dipping
Average Permeability	Not critical if uniform
Depth	> 2000 ft (LPG) to > 5000 ft (High Pressure Gas)
Temperature	Not critical

Limitations

The minimum depth is set by the pressure needed to maintain the generated miscibility. The required pressure ranges from about 1200 psi for the LPG process to 3000-5000 psi for the High Pressure Gas Drive, depending on the oil.

A steeply dipping formation is very desirable to permit some gravity stabilization of the displacement which normally has an unfavorable mobility ratio.

Problems

Viscous fingering results in poor vertical and horizontal sweep efficiency. Large quantities of expensive products are required. Solvent may be trapped and not recovered.

Table 6  
SURFACTANT/POLYMER FLOODING

#### Description

Surfactant/polymer flooding, also called micellar/polymer or microemulsion flooding, consists of injecting a slug that contains water, surfactant, electrolyte (salt), usually a cosolvent (alcohol), and possibly a hydrocarbon (oil). The size of the slug is often 5-15% PV for a high surfactant concentration system and 15-50% PV for low concentrations. The surfactant slug is followed by polymer-thickened water. Concentrations of the polymer often ranges from 500-2000 mg/L; the volume of polymer solution injected may be 50% PV, more or less, depending on the process design.

#### Mechanisms

Surfactant/polymer flooding recovers oil by:

- lowering the interfacial tension between oil and water
- solubilization of oil
- emulsification of oil and water
- mobility enhancement

#### TECHNICAL SCREENING GUIDES

##### Crude Oil

Gravity	> 25° API
Viscosity	< 30 cp
Composition	Light intermediates are desirable

##### Reservoir

Oil Saturation	> 30% PV
Type of Formation	Sandstones preferred
Net Thickness	> 10 ft
Average Permeability	> 20 md
Depth	< about 8000 ft (see Temperature)
Temperature	< 175°F

#### Limitations

An areal sweep of more than 50% on waterflood is desired.  
 Relatively homogeneous formation is preferred.  
 High amounts of anhydrite, gypsum, or clays are undesirable.  
 Available systems provide optimum behavior over a very narrow set of conditions.  
 With commercially available surfactants, formation water chlorides should be  
     < 20,000 ppm and divalent ions ( $\text{Ca}^{++}$  and  $\text{Mg}^{++}$ ) < 500 ppm.

#### Problems

Complex and expensive system.  
 Possibility of chromatographic separation of chemicals.  
 High adsorption of surfactant.  
 Interactions between surfactant and polymer.  
 Degradation of chemicals at high temperature.

Table 7  
POLYMER FLOODING

Description

The objective of polymer flooding is to provide better displacement and volumetric sweep efficiencies during a waterflood. Polymer augmented waterflooding consists of adding water soluble polymers to the water before it is injected into the reservoir. Low concentrations (often 250-2000 mg/L) of certain synthetic or biopolymers are used; properly sized treatments may require 15-25% reservoir PV.

Mechanisms

- Polymers improve recovery by:
- increasing the viscosity of water
  - decreasing the mobility of water
  - contacting a larger volume of the reservoir

TECHNICAL SCREENING GUIDES

Crude Oil

Gravity	> 25° API
Viscosity	< 150 cp (preferably < 100)
Composition	Not critical

Reservoir

Oil Saturation	> 10% PV mobile oil
Type of Formation	Sandstones preferred but can be used in carbonates
Net Thickness	Not critical
Average Permeability	> 10 md (as low as 3 md in some cases)
Depth	< about 9000 ft (see Temperature)
Temperature	< 200°F to minimize degradation

Limitations

If oil viscosities are high, a higher polymer concentration is needed to achieve the desired mobility control.

Results are normally better if the polymer flood is started before the water-oil ratio becomes excessively high.

Clays increase polymer adsorption.

Some heterogeneities are acceptable but, for conventional polymer flooding, reservoirs with extensive fractures should be avoided. If fractures are present, the crosslinked or gelled polymer techniques may be applicable.

Problems

Lower injectivity than with water can adversely affect oil production rate in the early stages of the polymer flood.

Acrylamide-type polymers lose viscosity due to shear degradation, or increases in salinity and divalent ions.

Xanthan gum polymers cost more, are subject to microbial degradation, and have a greater potential for wellbore plugging.

Table 8  
ALKALINE FLOODING

Description

Alkaline or caustic flooding involves the injection of chemicals such as sodium hydroxide, sodium silicate or sodium carbonate. These chemicals react with organic petroleum acids in certain crudes to create surfactants in situ. They also react with reservoir rocks to change wettability. The concentration of the alkaline agent is normally 0.2 to 5%; slug size is often 10 to 50% PV, although one successful flood only used 2% PV. (but this project also included polymers for mobility control). Polymers may be added to the alkaline mixture, and polymer-thickened water can be used following the caustic slug.

Mechanisms

- Alkaline flooding recovers crude oil by:
- a reduction of interfacial tension resulting from the produced surfactants
  - changing wettability from oil-wet to water-wet
  - changing wettability from water-wet to oil-wet
  - emulsification and entrainment of oil
  - emulsification and entrapment of oil to aid in mobility control
  - solubilization of rigid oil films at oil-water interfaces
- (Not all mechanisms are operative in each reservoir.)

TECHNICAL SCREENING GUIDES

Crude Oil

Gravity	13° to 35° API
Viscosity	< 200 cp
Composition	Some organic acids required

Reservoir

Oil Saturation	Above waterflood residual
Type of Formation	Sandstones preferred
Net Thickness	Not critical
Average Permeability	> 20 md
Depth	< about 9000 ft (see Temperature)
Temperature	< 200°F preferred

Limitations

Best results are obtained if the alkaline material reacts with the crude oil; the oil should have an acid number of more than 0.2 mg KOH/g of oil.

The interfacial tension between the alkaline solution and the crude oil should be less than 0.01 dyne/cm.

At high temperatures and in some chemical environments, excessive amounts of alkaline chemicals may be consumed by reaction with clays, minerals, or silica in the sandstone reservoir.

Carbonates are usually avoided because they often contain anhydrite or gypsum which interact adversely with the caustic chemical.

Problems

Scaling and plugging in the producing wells.  
High caustic consumption.

Table 9  
IN-SITU COMBUSTION

Description

In-situ combustion or fireflooding involves starting a fire in the reservoir and injecting air to sustain the burning of some of the crude oil. The most common technique is forward combustion in which the reservoir is ignited in an injection well, and air is injected to propagate the combustion front away from the well. One of the variations of this technique is a combination of forward combustion and waterflooding (COFCAW). A second technique is reverse combustion in which a fire is started in a well that will eventually become a producing well, and air injection is then switched to adjacent wells; however, no successful field trials have been completed for reverse combustion.

Mechanisms

In-situ combustion recovers crude oil by:

- the application of heat which is transferred downstream by conduction and convection, thus lowering the viscosity of the crude
- the products of steam distillation and thermal cracking which are carried forward to mix with and upgrade the crude
- burning coke that is produced from the heavy ends of the crude oil
- the pressure supplied to the reservoir by the injected air

TECHNICAL SCREENING GUIDES

Crude Oil

Gravity	< 40° API (normally 10-25°)
Viscosity	< 1000 cp
Composition	Some asphaltic components to aid coke deposition

Reservoir

Oil Saturation	> 500 bbl/acre-ft (or > 40-50% PV)
Type of Formation	Sand or sandstone with high porosity
Net Thickness	> 10 ft
Average Permeability	> 100 md
Transmissibility	> 20 md ft/cp
Depth	> 500 ft
Temperature	> 150°F preferred

Limitations

If sufficient coke is not deposited from the oil being burned, the combustion process will not be sustained.

If excessive coke is deposited, the rate of advance of the combustion zone will be slow, and the quantity of air required to sustain combustion will be high. Oil saturation and porosity must be high to minimize heat loss to rock.

Process tends to sweep through upper part of reservoir so that sweep efficiency is poor in thick formations.

Problems

Adverse mobility ratio.

Complex process, requiring large capital investment, is difficult to control.

Produced flue gases can present environmental problems.

Operational problems such as severe corrosion caused by low pH hot water, serious oil-water emulsions, increased sand production, deposition of carbon or wax, and pipe failures in the producing wells as a result of the very high temperatures.

Table 10  
STEAMFLOODING

Description

The steam drive process or steamflooding involves the continuous injection of about 80% quality steam to displace crude oil towards producing wells. Normal practice is to precede and accompany the steam drive by a cyclic steam stimulation of the producing wells (called huff and puff).

Mechanisms

- Steam recovers crude oil by:
- heating the crude oil and reducing its viscosity
  - supplying pressure to drive oil to the producing well

TECHNICAL SCREENING GUIDES

Crude Oil

Gravity	< 25° API (normal range is 10-25° API)
Viscosity	> 20 cp (normal range is 100-5000 cp)
Composition	Not critical but some light ends for steam distillation will help

Reservoir

Oil Saturation	> 500 bbl/acre-ft (or > 40-50% PV)
Type of Formation	Sand or sandstone with high porosity and permeability preferred
Net Thickness	> 20 feet
Average Permeability	> 200 md (see Transmissibility)
Transmissibility	> 100 md ft/cp
Depth	300-5000 ft
Temperature	Not critical

Limitations

Oil saturations must be quite high and the pay zone should be more than 20 feet thick to minimize heat losses to adjacent formations.

Lighter, less viscous crude oils can be steamflooded but normally will not be if the reservoir will respond to an ordinary waterflood.

Steamflooding is primarily applicable to viscous oils in massive, high permeability sandstones or unconsolidated sands.

Because of excessive heat losses in the wellbore, steamflooded reservoirs should be as shallow as possible as long as pressure for sufficient injection rates can be maintained.

Steamflooding is not normally used in carbonate reservoirs.

Since about one-third of the additional oil recovered is consumed to generate the required steam, the cost per incremental barrel of oil is high.

A low percentage of water-sensitive clays is desired for good injectivity.

Problems

Adverse mobility ratio and channeling of steam.

Table 11  
SUMMARY OF SCREENING CRITERIA FOR ENHANCED RECOVERY METHODS

	Oil Properties			Reservoir Characteristics					
	Gravity °API	Viscosity (cp)	Composition	Oil Saturation	Formation Type	Net Thickness (ft)	Average Permeability (md)	Depth (ft)	Temperature (°F)

11. Al-Bahar, M.A., et al.: “Evaluation Potential of IOR Within Kuwait,” SPE 88716, presented at the Abu Dhabi International Petroleum Conference and Exhibition (2004).

**Criteria for each EOR process are listed below.**

**Waterflooding**

Oil mobility > 0.1 md/mPa.s.  
Oil viscosity (at bubble point) < 2000 mPa.s.  
Oil saturation > 50%  
Current water oil ratio < 10 bbl/bbl  
No active water drive  
The condition of free gas/mobile water saturation:  
 $(1 - \text{connate water saturation} - \text{current oil saturation})^2 * (\text{oil viscosity}) < 0.5$   
Current pressure / Initial Pressure > 0.7

**Polymer Flooding**

Reservoir temperature < 158F  
Oil viscosity (at bubble point) < 150 mPa.s.  
Horizontal permeability > 50 md  
Oil saturation > 60%  
Current water oil ratio < 10 bbl/bbl  
No active water drive  
Local or no bottom water  
Local or no gas cap  
Water hardness < 1000 ppm  
Water salinity < 100,000 ppm

**Alkaline/Polymer Flooding**

Sandstone formation  
Reservoir temperature < 158F  
Oil gravity < 35 °API  
Oil viscosity (at bubble point) < 150 mPa.s.  
Horizontal permeability > 50 md  
Oil saturation > 50%  
No active water drive  
Local or no bottom water

Local or no gas cap  
Low clay content  
Water hardness < 1000 ppm  
Water salinity < 50,000 ppm

**Surfactant/Polymer Flooding**

Reservoir temperature < 158F  
Oil viscosity (at bubble point) < 150 mPa.s.  
Horizontal permeability > 50 md  
Oil saturation > 35%  
No active water drive  
Local or no bottom water  
Local or no gas cap  
Low clay content  
Water hardness < 1000 ppm  
Water salinity < 50,000 ppm

**Alkaline/Surfactant/Polymer Flooding**

Sandstone formation  
Reservoir temperature < 158F  
Oil gravity < 35 °API  
Oil viscosity (at bubble point) < 150 mPa.s.  
Horizontal permeability > 50 md  
Oil saturation > 35%  
No active water drive  
Local or no bottom water  
Local or no gas cap  
Low clay content  
Water hardness < 1000 ppm  
Water salinity < 50,000 ppm

**Nitrogen Miscible**

Depth > 1800 meter  
Oil saturation > 35%  
MMP (Minimum Miscibility Pressure) < (original reservoir pressure)  
Oil gravity > 35 °API  
Oil viscosity (at bubble point) < 2 mPa.s.  
Local or no gas cap present  
Initial pressure > MMP

**In Situ Combustion**

No fracture  
Local or no bottom water  
Local or no gas cap  
Net pay thickness > 3 meter  
Depth between 150 and 1800 meters  
Permeability > 50 md  
Oil transmissibility > 16 md-m/mPa.s.  
Oil viscosity (at bubble point) between 2 and 5000 mPa.s.  
Porosity > 18%  
Oil Content (Porosity \* oil Saturation) > 0.065

**Steam Flooding**

Depth < 1400 meters  
Permeability > 200 md  
Porosity > 20%  
Net pay thickness > 6 meters  
Current pressure < 1500 psi  
Oil viscosity (at bubble point) between 50 and 5000 mPa.s.  
Low clay volume  
Local or no gas cap present  
No fractures present  
Water oil ratio < 10 bbl/bbl  
Oil transmissibility > 16 md-m/mPa.s  
Oil Content > 0.065

---

**Immiscible Gas Flood**

Depth > 200 meter  
Oil saturation > 50%  
Oil gravity > 13 °API  
Oil viscosity (at bubble point) < 600 mPa.s.  
No active water drive  
Local or no bottom water  
Local or no gas cap

**Carbon Dioxide Miscible**

Local or no gas cap present  
Reservoir temperature > 86F  
MMP (Minimum Miscibility Pressure) < (original reservoir pressure)  
Oil gravity > 22 °API  
Oil viscosity (at bubble point) < 10 mPa.s.  
Oil saturation > 25%  
Depth > 600 meters

**Hydrocarbon Miscible Flood**

Depth > 1200 meter  
Oil saturation > 30%  
Oil density < 24 °API  
Oil viscosity (at bubble point) < 5 mPa.s.  
Local or no gas cap present
